THE DISTRIBUTION OF DIPHTHERIA IN MASSACHUSETTS.<sup>1</sup>

BY SAMUEL W. ABBOTT, M.D.,  
Secretary to the State Board of Health.

THE following paper is intended to present the principal facts which relate to the prevalence of diphtheria in Massachusetts, for the period of eighteen years from 1871 to 1888 inclusive, the chief point being its geographical distribution.

A brief general statement is presented as an introduction to the special topic.

The sources of information are, mainly, the annual registration reports, the voluntary returns of local health officers, and such personal inspections as have been made by the writer and others, under the direction of the State Board of Health.

## I. GENERAL DESCRIPTION OF THE STATE.

*Topographical and Climatic Features.*

The State of Massachusetts is one of the older and smaller States of the North American Union. In area it has a surface of about 8,000 square miles (21,000 sq. kilo.) or about two-thirds the size of Belgium.

As compared with the other States of the Union it is one of the least in area. There are but four smaller States. Texas has an area about thirty-three times as large. It extends over an average breadth of one degree in latitude, and three or more in longitude, the extremes of latitude being 41° 15' and 42° 53' N., and those of longitude being 70° and 73° 31' W.

The land of the south-east and the island portions is low and sandy, and rises gradually toward the western border, where the northerly portion of the Appalachian range of mountains traverses the State from north-east to south-west. The average elevation of the western county is not far from 1,000 feet, with occasional elevations of 2,000 and one of 3,500 feet.

The climate presents extremes which are trying to persons of delicate constitutions. Occasional temperatures of 20° below zero and 100° above are recorded. The mean average temperature at Boston is about 48°, and one or more degrees lower in the western counties. Sudden changes are common, and the passage from winter to summer is often rapid. The climate of the south-eastern portion and the two islands is much more equable than that of the interior. The ground often freezes to a depth of three feet or more in winter, and snow covers the ground to a depth of two feet or more, especially in the western counties. The average rainfall is from 42 to 44 inches.

The State has an irregular sea-coast line of about 250 miles.

## II. POPULATION.

The State was settled in 1620 by the English, and for nearly two centuries the English constituted by far the predominant nationality represented. Since 1840 immigration from various other sources has been rapid.

Massachusetts has also contributed more than one and one-half millions of its population to the Western States.

<sup>1</sup> Read at the Seventh Meeting of the International Congress of Hygiene and Demography, London, August, 1891.

In this paper it is to be understood that the data given includes fatal croup, since it is generally conceded by the physicians of Massachusetts that fatal croup, so far as the registration returns are concerned, cannot well be separated from diphtheria.

No census was taken until 1765, in which year the State had 238,195 inhabitants. The following table presents the number of inhabitants at each succeeding census:—

TABLE I.

POPULATION OF MASSACHUSETTS.	
Year.	Population.
1765 . . . . .	238,195
1790 . . . . .	378,787
1800 . . . . .	422,845
1810 . . . . .	472,040
1820 . . . . .	523,287
1830 . . . . .	619,408
1840 . . . . .	737,700
1850 . . . . .	994,514
1860 . . . . .	1,231,066
1870 . . . . .	1,457,351
1880 . . . . .	1,783,085
1890 . . . . .	2,238,943

By the State census of 1885 there was an excess of 76,373 females, so that the ratio of males to females was 100 to 109. The age periods 20–40 contributed more than one-half of this excess, a fact which is doubtless due to the emigration of the vigorous males of these ages to the Western States.

The population of the State at the census of 1880 consisted of 72.9 per cent. of persons of native birth, and 27.1 per cent. of foreign birth. Turning back to the previous generation, however, we find that of the parents 48.1 per cent. only were of native birth, and 51.9 per cent. were of foreign birth.

The accessions to the population by immigration during the past fifty years have been mainly from Ireland, the British North American Provinces, Scotland, Germany, France, Italy, and Sweden. For the past twenty years a large part of the accession from the British Provinces was of French Canadian origin.

The term *native* must be taken in a comparative sense, since the entire population is made up either of people of foreign origin, or their descendants of such class, to the number of nine or ten generations.

No allusion is here made to the aboriginal inhabitants, of whom there are less than 500 now living in the State, and of these but few are of unmixed Indian origin. They occupy two small sea-shore towns.

*Density.*

The State is more densely settled than any other State of the Union except Rhode Island. The average density of the population is 278.5 per square mile (by census of 1880). The population is very unevenly distributed, as is shown in Table V.

Massachusetts has followed the example of most civilized countries in the rapid increase of its urban as compared with its rural districts. Some of the cities and towns have doubled their population within a period of ten or fifteen years. On the other hand, in very many of the small towns, which occupy districts remote from railway travel, the population has for many years been stationary, and, in not a few, diminishing. Some towns have a smaller population than they had in 1790.

About thirty-eight per cent. of the population live within a radius of ten miles of Boston.

## III. VITAL STATISTICS.

The marriage, birth, and death-rates of the State for the past forty years are shown in Table II.

The birth-rates and death-rates of the urban and the rural population for the census years are shown in Table III.

TABLE II.

Periods.	Marriage rates (persons married).	Birth-rates.	Death-rates.	Excess of births over deaths.
1851-55 . . .	23.4	28.9	18.7	10.2

1888	.01	1.1	2.5	4.0	9.0	27.1	10.7

Table IV shows the mortality-rates from the principal infectious diseases for the twenty years ending with 1888:

## IV. THE COUNTIES.

We come now to the special topic which forms the title of this paper, the geographical distribution of diphtheria and croup in Massachusetts.

The term diphtheria does not appear in the registration reports of the State until 1858, a fact which has but little bearing upon the question of its prevalence at an earlier period.

From 1858 the annual number of deaths assigned to this cause rapidly increased until 1863, when 1,420 deaths were reported from this cause, and 1,231 in 1864. There was then a rapid decline till 1867, when there were but 251 deaths registered from this cause, and the annual number continued at quite a uniform rate of about 275 deaths for the next seven years, when it rose again to 2,610 in 1876 and 2,734 in 1877.

The diphtheria death-rate bears no relation to the general death-rate, except in the period 1862 to 1867; but in 1872, when the general mortality-rate was at its highest point and infectious diseases were generally very prevalent, the diphtheria death-rate was far below the mean, and in 1876 and 1877, when the general death-rate was quite near the mean, the diphtheria death-rate was at its highest point.

For the purposes of this paper the city and township will be considered chiefly as the unit of population for comparison, but, in the first place, the counties should be considered in a general way, although the county lines have but little sanitary significance.

The areas, the population, and density (census of 1890), and the diphtheria death-rates of the fourteen counties are presented in the following table:

TABLE V.

DEATH-RATES FROM DIPHTHERIA AND CROUP PER 10,000 OF THE POPULATION.

Counties.	Area in square miles.	Population, 1890.	No. to square mile.	Deaths, Diphtheria and Croup.	Total Population.	Child's under 5 years.
Barnstable .	373	29,172	78.2	332	5.8	69.0
Berkshire .	959	81,108	84.6	1,450	11.7	108.7
Bristol . .	557	186,465	334.8	2,366	9.4	90.0
Dukes . . .	124	4,369	35.2	10	1.3	20.0
Essex . . .	593	298,985	506.0	4,627	10.5	110.0
Franklin .	665	38,610	56.5	305	6.2	65.0
Hampden .	634	135,713	214.0	2,120	11.3	108.8
Hampshire .	572	51,859	90.6	617	7.3	79.0
Middlesex .	827	431,167	521.0	5,801	10.1	98.7
Nantucket .	65	3,268	50.3	110	16.4	253.6
Norfolk . .	494	118,950	240.8	1,485	8.5	86.0
Plymouth .	671	92,700	138.1	1,008	7.6	86.3
Suffolk . .	45	484,780	10,772.9	8,897	12.7	124.6
Worcester .	1,551	280,787	181.1	3,463	8.4	79.6
The State .	8,010	2,238,913	278.5	32,715	10.2	101.3

\* Death-rates per 10,000.

Some general features of the counties may be outlined, beginning with the western border of the State. Berkshire County consists mainly of high land, its

average level being nearly 1,000 feet above the sea. There are many mountains and hills of 1,500 to 3,500 feet, with deep valleys and swift watercourses. There is an abundance of forest land. There are a few thriving manufacturing towns. The manufacture of paper is largely carried on upon the pure, clear watercourses of this county. The population of the county slowly increases, but in many of the small towns remote from railway travel it has retrograded. The average density of the population is 85 per square mile.

The winters are long and severe, the snow often lying upon the ground in the forests, especially in the northern portion, until late in April.

The next three counties may be considered together. Franklin, Hampshire, and Hampden Counties lie upon the east and west sides of the Connecticut River, in the order named from north to south. The land in the two first named is generally higher than that in Hampshire, the southern county of the group. The Connecticut River divides them all nearly in twain, while four tributaries drain the areas upon each side, entering the Connecticut at nearly opposite points upon each side of the river.

The population of Franklin and Hampshire Counties is chiefly agricultural, while that of Hampden has a much greater manufacturing population, distributed in several rapidly increasing cities and towns.

The density of population in these counties is as follows: Franklin, 56.5 per square mile; Hampshire, 90.6 per square mile; and Hampden, 214 per square mile.

Worcester is the central county of the State, and the largest in area. It is mainly occupied by an agricultural population. It has one large and one small city, and several enterprising manufacturing towns. The land is generally high in the northern portions and lower in the southern.

Suffolk is the metropolitan county, and includes the seaport and city of Boston. The county contains about half a million of inhabitants, which gives, with its limited area, a density of about 10,000 per square mile.

Middlesex and Norfolk join Suffolk upon the north and south, and are quite densely settled in the suburban portions. The former has a large manufacturing population in some of its towns, and has many towns of extremely rapid growth. Some of them have doubled within the past decade.

Essex, the north-eastern county, has a bold, rugged sea-coast, several manufacturing cities of moderate size and healthy growth, one or two large fishing ports. The land, especially near the coast, presents but few elevations. The Merrimack River passes through its northern portion to the sea.

Bristol and Plymouth occupy the south-eastern part of the State (exclusive of Cape Cod). They include four thriving manufacturing cities. The growth of Bristol is more rapid than that of Plymouth. The climate is generally milder than that of the counties already named.

Barnstable County is Cape Cod, a long, flat, sandy peninsula, stretching east and northward seventy miles or more. It has no cities or large towns, and its population is diminishing by emigration. The principal occupations are fishing and the culture of cranberries. The climate is insular. Many of the towns are becoming places of summer resort, on account of the equable temperature and facilities for sea-bathing.

The two island counties have similar characteristics to Barnstable. They are sandy islands.

The average density of population of these three counties is about 70 per square mile.

#### V. CLASSIFICATION BY CITIES AND TOWNS.

The mortality-rates in the list of cities and towns have been compiled from the annual registration reports of the State for the period of 1871-1888.<sup>2</sup>

The number of municipalities having a city government at the beginning of this period was 14, and the number having such form of government at the close of the period was 28. Those having town governments at the beginning of the period were 322, and at the close 318.

A few changes have been made in the dividing lines of towns, for which due allowance has been made, where the changes included territory containing a considerable number of inhabitants, and a few new towns have been incorporated.

A table of mortality-rates from diphtheria is presented for the counties, but for the purposes of the present paper the town is taken as the unit of comparison.

Arbitrary methods must necessarily be taken for expressing the ratios of mortality, and in many instances, towns occupying an area of 50 or even 100 square miles of surface may have a rural population of one, two, or three thousand inhabitants, occupying but a small portion of this area. The population of 1880 is given as the basis of the ratio, since it is assumed as an average or mean for the period of eighteen years. The writer recognizes the fact that conclusions made from the statistics of small populations cannot be regarded as trustworthy, even for considerable periods of time. Hence the principal conclusions in this paper will be taken from large groupings, and not from the extremely small populations of the towns in rural districts.

There are some points which are worthy of notice in connection with the extremes at the top and bottom of the list.<sup>2</sup>

Of the fifteen towns which stand at the head of the list as having excessive mortality-rates from diphtheria and croup, in the period under consideration, five are small, or comparatively small, and contiguous towns in the north-west corner of the State.

These towns are mainly inhabited by a sparsely settled farming population, and their average level above the sea is much higher than that of the State in general. The lowest land in this district is at least 500 feet above the sea, and the average level of the district is not far from 1,200 feet above the sea-level. The district is very thickly wooded with forests of oak, pine, maple, and other woods, except in the valleys, which have a comparatively small area of cultivated meadows and low land. One small river flows through it in a general north-westerly direction, receiving many rapid mountain brooks as tributaries. There is one manufacturing town, a railroad centre, of 15,000 inhabitants.

Florida, which had the highest death-rate from these causes for the period, is a hill town of small population (159 in 1880). The Fitchburg Railroad passes under the town, from its eastern to its western border,

<sup>2</sup> It is impracticable to publish the complete list of cities and towns included in this table, on account of its length. It will appear in full in the Transactions of the Congress. A table (Table IX) of extremes is given at the close of this paper.

a distance of five miles, by means of the Hoosac Tunnel. The second town upon the list in point of prevalence is Spencer, an interior town of Worcester County, situated mainly upon a high hill, and having a comparatively dense population (7,466 in 1880), engaged mostly in shoe manufacture.

The third town, Freetown, is a town of comparatively small population (1,329 in 1880), in Bristol County, adjoining the manufacturing city, Fall River. The land is low and sandy.

Adams, Williamstown, and Hancock are all in north-western Berkshire, upon high land. Adams has a considerable manufacturing population upon the bank of the Hoosac River.

Webster is a manufacturing town in Worcester County, on comparatively low land. Ayer is a railroad centre in northern Middlesex. The land is quite level in the settled portion of the town.

Nantucket is both town and county; the population is a peculiar one, being the remnant of a once populous whaling and fishing port of nearly 10,000 inhabitants, now reduced to about 3,000 by emigration. Its birth-rate is very low, and its death-rate high, these exceptional conditions being produced by the emigration of the young and vigorous portion of the population, leaving the older portion, in whom the mortality-rate is high. The crowding together of the population into a densely compacted town upon a land-locked harbor undoubtedly contributes to the same result.

Turning now to the other extreme, four towns had no deaths from diphtheria during the period under consideration. All of these are small towns. Their chief characteristic is *inaccessibility*. Neither of them is upon or near a railway line, and public travel through them is very limited. Mt. Washington is cut off from the rest of the State and from the Housatonic Railway by a range of high hills. Chilmark is a remote town upon the island of Martha's Vineyard, at a distance from the points of summer resort.

Dividing the State by a more general classification into rural and manufacturing towns, there are 254 of the former class, and 92 of the latter. The general characteristics of these two classes are as follows:

*Rural Towns.*—These are mainly towns of small population, distributed over an average area of nearly thirty square miles for each township. The principal occupation of the population of these towns consists of dairy-farming, market-gardening, and other branches of agriculture.

The entire population of this class of towns in 1880 was 110,664, giving an average for each of the 254 towns of 1,755 inhabitants. Five only, out of this number, had more than 5,000 inhabitants in each by the census of 1880. A few of these towns are summer resorts, either upon the sea-coast or in the inland region. Some of the towns of this general class have increased slightly in population in the past twenty-five years, many have remained stationary, and a considerable number have slowly decreased. The younger and more vigorous producing part of the population has emigrated either to the cities or to the Western States.

(To be continued.)

The Canadian government has warned steamship companies that it cannot undertake to provide for destitute immigrants at the public expense, and that the companies may be ordered to return them.

## LAPAROTOMY, WITH REMOVAL OF CANCER OF THE OVARY.<sup>1</sup>

BY CHARLES F. STRONG, M.D.

THE specimen with which I accompany these notes, was removed to-day from a girl of twenty-one, whom I first saw in February, 1891. The history given at that time was that about the last of the preceding November, while dressing, she noticed a sensation of hardness on the right side of the abdomen, but without any pain or discomfort whatever; nor had the increase in her size, which to my eye was very marked, been observed by any member of her family. She had always led an active outdoor life, and was, so far as she knew, thoroughly healthy, with the exception of this hard lump. Menstruation was regular every four weeks, lasting five days, there being no change in that respect since November. The pain which she had when unwell never sent her to bed or interfered with whatever employment she might have at hand. She was entirely free from backache, abdominal pain or discomfort. Bladder and rectal symptoms were also wanting.

The abdomen presented an irregular, lobulated enlargement, from the navel to the public bone. Abdominal palpation, with the patient under ether, showed two large lobes, the right much the larger, and several small and more or less movable lobules above and to the left of these two larger lobes. These lobules were about the size of a kidney. The whole size of the tumor, as apparent under the examination, was about that of an adult head. On vaginal examination, a multi-lobular tumor, with close connection to the uterus, but movable in a limited degree, could be felt filling up Douglas's fossa and encroaching upon the vagina from all sides, extending deep in the abdomen, and also high above the navel. The uterus was crowded down nearly to the vulva and to the right. It was not movable as a distinct organ from the tumor. The mass seemed to spring, without a pedicle from the uterus on the left side, at or near the junction of the cervix and body. The cavity of the uterus measured three and one-half inches. The growth pressed slightly upon the rectum.

Taking into consideration the girl's age, there was a certain element of doubt thrown upon the diagnosis, which otherwise would have been almost unhesitatingly pronounced multiple uterine fibroids, and which I subsequently learned had been so considered by every physician under whose hands she had previously come. Being quite confident that this was the condition, and, having in view the freedom from any symptoms, I felt that temporizing measures would be the best here, rather than the removal either of the tubes and ovaries or of the growth itself, which seemed to present all the difficulties that would render the operation one of danger. In this conclusion I had the concurrence of the patient and her family, and prescribed ergot. There were no untoward symptoms until the latter part of March. One menstrual period had been passed with absolutely no pain and with normal flow. With the second period there was some pain, and the patient localized a good deal of discomfort, at times absolute suffering, upon the left side, about midway between the navel and the anterior superior spine of the ilium. I could not discover any change in the size or relations of the growth to account for this, and attributed it

<sup>1</sup> Read at the meeting of the Obstetrical Society of Boston, May 9, 1891.

rather to over-exertion at the time she was unwell, which had possibly caused a slight peritonitis, as her temperature was a little elevated. Contrary to my expectations, this pain did not improve with rapidity. There were remissions of it, but the returns were more severe. The patient eventually began to lose flesh rapidly, and, at the same time, appetite and courage. I had her go to her home in the country, but the change did not prove beneficial, and was really disadvantageous, because it removed her from my immediate care, so that a longer time than I should have otherwise have allowed to elapse passed by before I saw the patient again, which was in the latter part of April. She was then having a temperature of  $100^{\circ}$  to  $101^{\circ}$ , had become strikingly emaciated, the growth had increased very materially, and in parts felt elastic, as though fluids were present.

On May 9th I operated. The incision went through a very much thickened peritoneum; and came upon a large, irregular, semi-solid tumor, which was aspirated with no result. The tumor extended down behind the uterus, filling both sides of the pelvis, up to the liver on the right side and the stomach on the left, and pressed up the diaphragm, causing compression of the lungs. The incision was extended one and one-half inches above the umbilicus, and the tumor rapidly dissected out. Several large adhesions to the intestines, omentum and abdominal walls were clamped and tied. The pedicle, which was found on the left and included all the vessels of the broad ligament, was as thick as the wrist. It was tied with a shoemaker's stitch, cauterized and dropped back. The pedicle, upon its cut surfaces, was very fibrous, and as much as possible of this tissue was cut away. There was some hemorrhage complicating the operation, from the adhesions, and from the vessels of the broad ligament retracting. The ovary of the right side contained one retention cyst, which was not disturbed. The weight of the tumor, twelve hours after removal, was fifteen and one-half pounds.

The report of Dr. Whitney, to whom the specimen was submitted, was that the tumor was cancer of the ovary, and that the pedicle showed no evidence of disease.

The condition of the patient was extremely bad after the operation for some hours. Then she rallied, and made a convalescence which was interrupted only once by a slight attack of peritonitis, induced by morphia being given, contrary to orders.

The interest of this case lies in the possibility of having made a differential diagnosis ten weeks earlier than I did, that is before I operated. The sensation imparted by the tumor to the examining hands, both abdominally and vaginally, was that of a firm, fibrous, elastic mass. The girl's age was against it being a fibroid. The youngest I have seen before of pure fibroid tumor has been twenty-three years. But the freedom from pain; the comparatively slow growth of upon her own part or her mother's, that there was the tumor which did not arouse suspicion before, either any abnormal enlargement; the increased depth of the uterus; the inability to differentiate the uterus from the tumor as having a separate degree of mobility, — all pointed, to my mind, very conclusively to the existence of fibroids only. The question of making an exploratory incision I did not feel to be worthy of consideration, because if it were a fibroid and were giving no trouble, and were of this excessively slow

growth, it was, to my mind, far better to leave matters as they were. On the other hand, were it a tumor of unknown origin, an exploratory incision would, of necessity, have been followed by this operation; and, while it would have been proper, yet it would have been one for which neither the patient nor her family were at that time prepared. The occurrence of cancer of the ovary, and especially of cancer of the ovary at this early age, and a cancer of this variety, is rare. I have been able to find but very few recorded cases in which the diagnosis has been substantiated by microscopical examination. The growth was of such a marked degree of malignancy that, of course, its return is to be greatly feared. The point of interest is that the pedicle, although thick and large, was absolutely free from disease, showing that that was all removed, so that the one point of infection possible is along the adhesions to the other pelvic organs. One cyst was torn slightly and a very small portion of its contents escaped into the abdominal cavity. This was immediately thoroughly washed out, so that I feel that the chance of infection in this way was entirely removed.

NOTE. — June 22d. The patient has steadily improved, and, upon vaginal examination to-day (six weeks after the operation), no evidence of thickening could be discovered upon either side of the pelvis. There is no pain, and she is enjoying her usual routine of life.

September 1, 1891. The patient has gained nineteen pounds in weight during the past month, and is perfectly well.

## THE APOSTOLI METHOD OF TREATMENT: ITS TECHNIQUE.<sup>1</sup>

BY WALTER L. BURRAGE, M.D.

ALTHOUGH the Apostoli method of treatment, as ordinarily spoken of, refers to the treatment of fibroid tumors of the uterus with electricity, strictly speaking it should have reference to the treatment of uterine disease with electricity by the most recent and approved methods. For to Apostoli in chief are due the accurate measurement of electrical doses; the application of the electricity most nearly at the seat of disease; the possibility of the use of high intensities by means of the abdominal clay plate at the inactive pole; and, above all, the elimination of danger by the employment of strict antiseptic precautions. He has elaborated the details of the treatment, and has carried it out with painstaking attention and an enthusiasm that has gained for him and his methods a wide notoriety and a host of eager fellow-investigators the world over.

It is my purpose in this paper to treat in a practical way the methods of applying galvanic and faradic electricity in uterine disease.

At some future time I hope to report results with this treatment, to add my testimony to its merits as a therapeutic agent. It has been a good deal slighted in the past, principally from faulty methods and a lack of knowledge of electricity on the part of those who applied it, and is only now taking the place it deserves as a routine means of treatment in gynecology.

Before speaking of the necessary apparatus, I should like to say a word or two about electricity itself, for it is very essential to have a proper understanding of your medicine and its dosage before prescribing.

I must take it for granted that the theory of the

<sup>1</sup> Read by invitation before the Obstetrical Society of Boston, May 9, 1891.

voltaic cell is known to you all. The cell consists of a plate of zinc and a plate of carbon in a jar of acidulated water, and separated one from the other by some non-conducting material. The zinc plate is the positive element, the carbon the negative. Positive electricity flows down the positive element, which is the same thing as negative electricity flowing up it, whence it happens that the negative pole of the battery is at the zinc plate. So the carbon is the negative element and the source of the positive pole. The electricity passes through the water from the positive to the negative element, decomposing it into its constituents, hydrogen and oxygen. The hydrogen gathers in bubbles on the negative element, and the oxygen on the positive element.

Suppose the current starts from the positive element. In flowing through the water to the negative element it meets a certain amount of resistance, and this is the internal resistance of the cell; then passing up the negative element it emerges from the cell as positive electricity, and in its course back to the cell — back to the negative pole — it encounters further resistance in the conducting media. If a copper wire, the resistance — called now the external resistance — is very slight because copper is a good conductor; if, on the other hand, it is a portion of the human body the resistance may be considerable.

The elements of a number of cells may be coupled, so that the electricity obtained from the battery will be a current of quantity or a current of tension. By coupling all the zincs together and all the carbons together we get a current of quantity. But if the elements are coupled in pairs, a zinc with a carbon and so on, we get a current of tension. What we want in gynecological electricity is a current of high tension and of moderate quantity.

Now there are certain electrical terms that is necessary to understand in order to get a definite idea of the subject. These are the ohm, the volt and the ampère.

The *ohm* is the unit of measure of resistance; it is the amount of resistance that would be offered to the passage of a current of electricity by a column of mercury one square millimetre in diameter, and one metre and a fraction long, at 16° Centigrade.

The *volt* is the unit of measure of electro-motive force — of the pushing power of the electricity; it corresponds to "pounds-pressure" in speaking of a steam-boiler. The electro-motive force may be likened to the pressure in a pipe emptying a cistern of water. The pressure would be the same, no matter what the size of the cistern, provided that the water was maintained at the same height and the pipe of a constant diameter. The volt is the amount of electro-motive force necessary to drive a current through an ohm of resistance.

The *ampère* is the unit of measure of current. It is the amount of current that results from a volt of electro-motive force passing through an ohm of resistance. In medicine we use the thousandth of an ampère, the millampère, as a unit, our currents being comparatively weak.

There is a simple rule by which we can determine the current strength, knowing the electro-motive force and the internal and external resistance of the battery; it is that the electro-motive force divided by the sum of the internal and the external resistance is equal to the current, and it is called Ohm's Law. In the human body the resistance is very high, the skin offering

the greatest opposition to the passage of the current; a dry skin is more resistant than a wet one. In passing a current through a fibroid tumor from the interior of the uterus to the surface of the abdomen there may be all the way from 100 to 200 ohms of resistance. The current pursues the path of the least resistance; generally that is the most direct path also, but not necessarily, as may be the case with a fibroid of great density and high resistance. A current from a vaginal electrode placed near it may pass to one side and not enter the tumor at all; hence the advantage of intra-uterine treatment and treatment by puncture.

There is an active and an inactive pole in gynecological electricity. The active pole is applied in the vagina or uterus, the inactive to the surface of the body. We expect no effect from the inactive pole beyond a mild counter-irritation; it simply serves to close the circuit. We may make either the positive or the negative pole the active one, as we choose.

As to the therapeutic action of the two poles: at the negative, hydrogen gas and alkalies are attracted from the tissues; at the positive, oxygen gas and acids gather. The negative is the liquefying, and the positive the coagulating pole. Besides the action at the poles there is the interpolar action, the action on all the tissues through which the current passes, most marked near the active pole.

According to Apostoli, the negative pole in its interpolar action is stimulating and congestive and favors absorption by increasing the blood-supply; in its polar action it is markedly electrolytic, producing chemical decomposition and cauterizing with lower intensities than the other pole.

The positive pole in its interpolar action is sedative, anticongestive, hemostatic. It is used to allay inflammation and drive out pain. In its polar or local action it is styptic with moderate intensities, and caustic and hemostatic with high intensities. It is used to check hemorrhage when applied to the interior of the uterus. Apostoli and Laquerrière have determined that the positive pole has a marked germicidal action, much more so than the negative. Its polar action is the important one; the interpolar action secondary.

Apostoli does not apply the active pole in the vagina any longer, considering the intra-uterine method superior. It seems to me that, in certain cases, as, for instance, when we wish to place the active pole as near as possible to a mass of exudation, that the vaginal method is preferable. By using a clay-covered vaginal electrode, high intensities (100° or over) may be employed without danger to the vagina. With the old-fashioned brass ball covered with chamois skin or absorbent cotton, it was possible to make a deep ulcer with a current of 30°. When using the positive pole in the vagina, it is well to dip the electrode in a solution of bicarbonate of soda before using, to neutralize the acids that are attracted to this pole.

*Gadonism.* — For apparatus, it is better to have a battery of from thirty to fifty cells. I consider a battery of forty Leclanché or Law cells as the best. Each cell should have a capacity of about a quart. Such a battery gives an even and reliable current, and is the least trouble to take care of. For portable batteries, that made by Gaiffe, of Paris, with zinc and carbon elements in a solution of bisulphate of mercury, and having a convenient collector, seems to me the best. Waite & Bartlett, of New York, make a good plug and socket battery.

As a current measure it is important to have a trustworthy instrument. Who would think of giving a powerful drug without carefully measuring the dose? It will be apparent, by bearing in mind Ohm's Law, that the number of cells of a battery used in a treatment is no accurate measure of the current, for the resistance is never twice alike. What we do with the milliamperè meter is to measure the actual current that is passing in the circuit in which the body or a part of the body is included.

The meters made by Gaiffe, Engelman, McIntosh, and Waite & Bartlett are all to be relied on. The instrument should be calibrated to measure up to 250° or 300°. To regulate the current either a collector, a current controller, or a water rheostat may be used. Waite & Bartlett make a good collector, and the water rheostats of Keith or Bailey are simple and cheap. I have had no experience with current controllers. There is one made by Fleming, of Philadelphia, that is well recommended.

**Electrodes.**—For the inert pole the clay plate of Apostoli is best. This should be large where high intensities are to be used, eight inches by ten inches is a convenient size. I prefer the modification of Dr. Goelet, of New York, who has placed the clay in a rubber covering, making it much easier to handle.

For internal electrodes the most useful of all is the non-corrodible platinum. Just now platinum is about as costly as gold, and difficult to procure at that. A convenient substitute is iron treated by hydrogen by a special process. The tips of this electrode may be renewed often if they become corroded by the positive pole; they cost a matter of twenty-five cents each. A two and one-half inch tip is most generally useful. Tips are also made from block tin. They are cheap, flexible, and stand the positive pole well. For the negative pole alone a tip of copper, nickel-plated, is very serviceable. A vaginal electrode should form part of an electrical outfit. That devised by Goelet is the best. It consists of a ball of carbon covered with clay and absorbent cotton.

For galvanic puncture of fibroids and pelvic exudation the best electrode is that made for Apostoli by Gaiffe. It consists of a long steel needle, a millimetre and a half in diameter, and tipped by a sharp gold point one millimetre in diameter and half a centimetre in length, this point being insulated from the main shaft of the needle by a hard-rubber collar one centimetre long and of the same diameter as the point. The insulation insures to the vagina and peritoneum at the point of puncture immunity from caustic action. The needle is held in a universal handle—the shaft being insulated from the vagina by a sheath of hard rubber. This needle, I have found, causes less pain than does a needle not provided with insulation at the place where it passes through the vaginal and peritoneal coats.

**Faradism.**—The faradic or induced current differs much from the galvanic, though it has many similar effects. When an insulated copper wire, its ends connected with the poles of one or two voltaic cells, is wound round a bunch of soft-iron wires, forming the primary coil, the current passing through the wire will render the soft iron a magnet. Now, if another coil of copper wire is slipped over the first coil, it will be found that at the time of making the circuit, a current is flowing in the wire of the second coil in an opposite direction to that in the first. This current

lasts but an instant. At the moment of breaking the circuit another current is induced.

Taking advantage of these facts, it is customary to interrupt the current more or less rapidly by means of the rheotome, or vibrator, a simple mechanical device depending for its action on the magnetizing and demagnetizing of the soft iron. When the secondary coil is made of large coarse wire and comparatively short, we get a current useful in contracting a uterus or where stimulation is needed. When the secondary coil is made of fine wire and very long,—Engelman uses a coil made of 600 metres of wire,—we get a current very useful in relieving pain. The choice of poles of the faradic battery is of little consequence—no especial difference in their action has been determined.

The secondary current cannot be measured like the primary, and the only means we have of determining whether at one time we are giving the electricity stronger or weaker than at another is by noting how much we move the secondary over or off the primary coil.

For the application of faradism it is necessary to have a battery constructed on the Dubois-Reymond plan, that is, with a stationary primary coil over which the secondary coil is slipped to increase the current. It is best to have two or three coils. If two, one should be wound with a long and fine wire, the other with a short and coarse wire. The Engelman battery has three coils, the third being of medium-sized wire, and of medium length. I use a battery made for me by Waite & Bartlett, and having two coils.

For electrodes, two are necessary, both bipolar, that is, with both poles on one staff and insulated one from the other; one electrode is large for the vagina, the other smaller for intra-uterine applications. The advantages of the bipolar method of applying faradism are to my mind considerable. The entire current is concentrated where you wish to use it, and it is less trouble to administer.

The approximate cost of an electrical outfit is from \$75 to \$100, though it is possible to spend twice or three times this sum.

**Operative Detail.**—The important points are, strict attention to asepsis, a careful choice of the active pole, and graduating the dose according to the susceptibility of the patient.

Let us follow the steps of the treatment in a case of fibroid treated in the office. The patient is placed on the table on her back, with her hips at the edge. The vulva and vagina are thoroughly irrigated with a solution of corrosive (1-5000) from a douche-pail hanging conveniently near. The water from the vagina is caught in a basin or small bed-pail or allowed to run down over a Kelley apron to a pail on the floor. When for any reason it is inconvenient to give the douche, I am in the habit of swabbing the vagina and vulva freely several times with large pieces of absorbent cotton soaked in corrosive and held firmly in a pair of Bozeman's forceps. The perineum is hooked back with the left forefinger while the cotton is carried over the entire surface of the vagina. Next, the clay plate is placed on the abdomen by the nurse, it having been previously warmed over the register or treated with hot water in a shallow pan. A photographer's developing pan is useful for this purpose, and serves to hold the plate when not in use.

The operator now tests his battery. If it is one where cell after cell is taken into the circuit sepa-

rately, either by means of a collector or by the plug and socket arrangement, it is better to test each cell. To do this, put a feeble resistance in the circuit from zero to cell No. 1, and note the deflection of the galvanometer needle. Repeat the operation with cells 1 and 2, and so on through the series. When the entire series of cells is used at once it is sufficient, as far as safety against shock goes, to make a high resistance in the rheostat, and note whether the needle is deflected when the circuit is closed. It is to be said that it makes no difference whether the rheostat and galvanometer are connected with the negative or the positive pole, so long as they are in the circuit; the former is used to graduate the current and the latter to register its strength. It is especially important that the ends of all the conducting wires should be free from grease or other non-conducting material, and that they should fit tightly into their sockets so that the circuit may not be broken during the treatment.

After washing his hands the operator is ready to introduce the internal electrode. This may be done with the patient on the back, either by touch or with a Goëlet depressor speculum by sight; or with the patient on the side and the Sims speculum. In the majority of cases I prefer to pass the electrode by touch.

*Cleansing the Electrode.*—Wash it after each application. Just before using, plunge it in boiling water, to which a little washing soda has been added, for a few minutes. For this purpose an ordinary quart tin can over a kerosene stove answers very well. Then it is cooled off in a corrosive solution (1-2000), and introduced. Great care should be exercised not to hurry or to do any violence to the uterus while passing the electrode.

The same antiseptic precautions are to be observed with the needle and its sheath used in puncture. In cases of hæmorrhage from the uterus an electrode of gas carbon is often used to advantage, because this substance may be made into tips of various sizes to fit different uterine canals, and it is not affected by the positive pole. On account of the porous nature of the carbon, it is well to dip it in iodoform and ether before its introduction.

In cases where there is severe flowing it is important to make the application to as much of the internal surface of the uterus as possible. For this purpose the handle of the carbon electrode is provided with notches an inch apart, the length of the carbon tip. The operator makes an application of five minutes with the tip at the fundus, then withdraws the electrode till his finger at the cervix feels the next notch, and repeats the application, and so on until the whole length has been treated.

Next make the connections between the clay plate, galvanometer, battery and internal electrode, and turn on the current gradually. At the end of the treatment decrease the current in the same way, taking a minute of the five minutes of treatment for increasing and decreasing. With high intensities, when possible, I like to have the active pole entirely in the cavity of the uterus, and thus avoid cauterizing the cervical canal, because of danger of subsequent stenosis, and also from the fact that the cervix is so much more sensitive to electricity than the fundus. The electrode should be held steadily in the same place during the entire treatment except in cases where it is desirable to cauterize the entire cavity, as for hæmorrhage, just alluded to.

The operator should watch the galvanometer and the face of his patient closely while the current is passing. Oscillation of the needle means changes in the resistance, or breaks in the circuit. The treatment should not cause much pain.

After the clay has been removed and the abdomen rubbed dry, the patient is directed to lie down for from half an hour to two hours, more or less, depending on the amount of reaction. In out-patient work this rule is often difficult if not impossible to carry out, yet in my experience no harm has come from disregarding it. At the first treatment it is well to insist on its observance.

The galvanopuncture is made as follows: the patient is directed to take a corrosive douche (1-5000) twice a day for a day before the treatment. She is given the preliminary douche as in other cases. Select a point in the cul-de-sac where there is no arterial pulsation to be felt, taking care not to puncture in the neighborhood of the rectum. It is not well to puncture anteriorly, because of danger of wounding the bladder. The needle is fixed in its handle so that half an inch projects beyond the sheath. The sheath is then drawn forward so as to protect the point, and is passed along the left forefinger to the spot selected. Make the puncture quickly. The current should be turned on very slowly, and the treatment should last from five to seven minutes. If there is much pain the patient may hold a handkerchief with ether to her face. If there is oozing afterwards apply Churchill's iodine to the spot. Place a piece of iodoform gauze, with a thread attached, in the vagina, having first swabbed out with corrosive. The gauze should be removed by the patient at the end of forty-eight hours, and a corrosive douche taken.

I have repeatedly made the puncture in my office and at the clinic, and sent the patient home after a rest of an hour or two, without bad results. This plan will answer in selected cases. Where possible, I should advise rest in bed for twenty-four hours. Another puncture should not be made sooner than a week or ten days.

As to the dosage of electricity, it is important to remember that different patients tolerate the current in a very different manner. A stolid, phlegmatic Russian Jew, with a large tumor, will bear a current of 150° or over without flinching, whereas a neurotic, hysterical lady, with a small tumor, may have considerable pain with a current of 10°. From what I have seen of Dr. Apostoli's work, and his writings bear me out in the statement, he applies very high intensities only in cases of large tumors, and intensities of over 200° rather exceptionally. A majority of cases—cases of subinvolution, endometritis, small tumors and pelvic exudations—are treated with a current of from 60° to 100°, depending on the individual patient.

It is not sufficient to introduce an electrode and turn on a current hap-hazard, any more than it would be considered good treatment to give all patients suffering with secondary syphilis a uniform dose of mercury. You have to be guided by the tolerance in the individual patient.

So with regard to the frequency of the applications, there is no cast-iron rule to follow. Some patients can be treated twice or three times a week to advantage; others, only once a week; and still others not as often.

The operative technique is not especially tedious.

Using high intensities — by that I mean currents of over 50° — the treatments average five minutes each actual time of current passing. At my clinic at the Free Hospital for Women, I treat about five patients an hour.

The requisites for successful electrical treatment are, besides a working knowledge of gynecology, suitable apparatus and an acquaintance with electricity.

## Medical Progress.

### RECENT PROGRESS IN THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D.

#### ON THE PREPARATION AND USE OF OINTMENTS IN DISEASES OF THE SKIN.<sup>1</sup>

DR. L. DUNCAN BULKLEY has published a practical and suggestive article on the above subject, and gives many hints of value to practitioners. The application of ointments constitutes such a large element in the treatment of diseases of the skin, by the profession at large, that it seems desirable to present a few words of caution concerning their preparation and employment, for want of success often results from the improper compounding or application of one or another of this class of remedies.

It is better not to trust to any artificial means for preserving the freshness of ointments, but to secure sweet and good material and always to reject that which is at all old, or ointments which have been long prepared. It is important to avoid the slightest rancidity in ointments, and it is better to order ointments to be freshly compounded of the strength desired, rather than to take those officially prepared and kept in stock.

Among cerates, which are in some respects more valuable for ointments for most skin affections than lard, we have two: *ceratum simplex*, consisting of white wax 30 parts, lard 70 parts; *ceratum cetacei*, which is composed of spermaceti 10 parts, white wax 35 parts, and olive oil 55 parts. To these should be added *unguentum cetacei*, which is very like the latter, only somewhat softer. These all have considerable body, and when spread on the skin form a protective coating, more suitable for many conditions than lard alone; but the first mentioned or simple cerate is far too hard for easy application in most diseases of the skin. The *glyceritum amyli*, composed of starch 10 parts and glycerine 90 parts, is a good basis for ointments when fatty substances are not well borne, or when it is desirable to remove the application frequently with water. Combined with oil of cade 25 parts, sapo viridis 15 parts, and glycerite of starch 60 parts, it makes a most valuable application in psoriasis, which can be well rubbed in at night and washed off completely in the morning.

The *oleum theobromæ* is ordinarily but little used in compounding ointments. It is particularly useful when added, in about a quarter part, to ointments for use on the hairy scalp to give them a low melting-point and to aid in forming a protective coating over the skin. When employed in too large proportion it will prove irritating to many skins.

Under the head of "ointments" we find but two

preparations in the pharmacopœia: the *unguentum simplex*, composed of lard 80 parts and yellow wax 20 parts, and *unguentum aque rosæ*, of expressed almond oil 50 parts, spermaceti 10, white wax 10, rose-water 30 parts. The *unguentum simplex* is a good combination — much better for general use than simple lard; but, on the other hand, it is often found to be too hard, and ointments made with it will often be difficult of application, and when made up for some time with other ingredients, it will become too stiff for ready use; as ordinarily kept in drug stores it has not infrequently been found quite rancid.

The best ointment of all, when fresh and properly made, is the *unguentum aque rosæ*, the cold-cream of the pharmacopœia. But some judgment and skill is necessary in its preparation, for unless very perfectly compounded, with prolonged rubbing together of the ingredients, the ointment will not be perfect; in summer, also, it will require rather a larger proportion of the spermaceti and white wax in order to have the proper consistency for a perfect application. Very frequently, when the skin tends to be too dry, a portion of the water may be replaced with glycerine. Occasionally the odor of rose-water is not agreeable to the patient, and simple distilled water may be used in its place. The water held in this ointment is undoubtedly an important element in its remarkable effects upon the skin, for the *ceratum cetacei* and *unguentum cetacei* have quite a similar composition, but are by no means agreeable to most skins.

When the various products of petroleum known in the pharmacopœia by the general name of *petrolatum*, were introduced, it was thought they would furnish the best possible bases for ointments, and that they would rapidly supersede all other excipients; in Dr. Bulkley's opinion they will never supplant those already mentioned and others of recognized value. They are by no means always agreeable and non-irritating to the skin; indeed, many individuals are found who cannot bear them on the skin at all. Most of them have not body enough to form good ointments, although for simple innunction, as a lubricant, or for the application of carbolic acid to the skin as an antipruritic, vaseline serves the purpose very well.

Recently when lanoline and subsequently agurine were presented to the profession, it was expected that this substance would replace others as an excipient for ointments. But again we have been disappointed, and lanoline forms but a very small portion of a base of ointments used by those especially occupied with diseases of the skin. It is too sticky and not easy of application, and, moreover, it will often prove irritating to a delicate skin. While it was thought to afford a means for the more ready absorption of medicaments, more experience has shown this to be questionable. Indeed, in some experiments by Brooke, it was shown that the substances incorporated with lanoline were the slowest in entering the system. Lanoline is, however, useful as an addition to certain ointments, in the proportion of about twenty per cent., to give an adhesive quality to them, thus securing a firmer and more adherent coating for affected parts.

Of some forty official ointments, very few can be prescribed, as they are, in diseases of the skin. Thus the carbolic ointment is made of a strength of ten per cent., which is far too strong for most skins, whereas the tannin ointment of the same strength is too weak to be of real service. Belladonna ointment is also of

<sup>1</sup> Therapeutic Gazette, August 15, 1891.

the same strength, and is capable, if used at all freely, of producing serious constitutional effects. Also, the official ointment of chrysarobin should be diluted for most skins. Eight ointments are official containing preparations of mercury. Of these, the blue ointment, containing fifty per cent. of metallic mercury, is well known and of great value; but for inunction on most skins it requires dilution by one-half, in order not to excite too much irritation. White precipitate ointment has commonly to be diluted two or three times, even in psoriasis and seborrhœic eczema. The red iodide ointment is of fair strength, but to be effective in lupus, or where its corrosive power is required, it should be employed much stronger. Citrine ointment, one of the best known of the mercurial applications, is far too strong to be freely used. When diluted two to four times, it often serves a good purpose in reducing infiltrations in the skin. The yellow and the red oxide of mercury require to be very greatly diluted for use about the eyes. The single ointment of iodine is a good preparation, containing a trifle of iodide of potassium. A prescription which is of great service in reducing glandular enlargements in syphilis, is a mixture of iodine ointment with the ordinary mercurial ointment in equal parts. When well rubbed together, an ointment of the green iodide of mercury is made, which acts much more quickly than either of the ointments alone. For delicate skins it may require some dilution, but generally it is well borne. It is useful as a parasiticide in ring-worm and favus of the scalp.

The *unguentum picis liquidæ* is an excellent remedy, composed of equal parts of tar and suet; but it is far too strong for general use undiluted. When combined with oxide of zinc and rose ointment it forms one of the most perfect applications known for a large share of cases of subacute eczema, both in children and in adults:

R	Ung. picis	.....	3 ij.
	Ung. zincæ oxidæ	.....	3 ss.
	Ung. aquæ rosæ	.....	3 iv. M.

The ointments of the carbonate lead and iodide of lead, each ten per cent., are also good combinations. The latter is certainly an excellent means for causing absorption of enlarged strumous glands. The stramonium ointment, containing ten per cent. of the extract of stramonium, is likewise a good application, and forms a most valuable base for combination with acetate of lead and opium in the treatment of hamorrhoids. There are four ointments containing sulphur, only one of which, the *unguentum sulphuris*, containing thirty per cent. of sublimed sulphur, is well known or much used. This is also too strong for direct application to most skins; diluted two or three times with a little stearin, and perhaps a little tar ointment, it forms an excellent treatment for scabies, but the more agreeable applications of naphthol and resorcin have largely taken its place in dermatological practice. The oxide of zinc ointment of our pharmacopœia is a fairly good preparation. It is made of benzoated lead, which is not agreeable to all skins; it is sometimes rancid and therefore irritating, where a freshly prepared zinc ointment and cold cream is grateful and healing.

Dachylon ointment, when freshly and properly made, is one of the most valuable means of local therapy known for many diseases of the skin. The preparation made according to the original preparation of

Hebra, and given in the German Pharmacopœia, is a soft, buttery ointment, easily spread, and of a delightfully soothing character to most skins, and is decidedly superior to the ointment made according to the United States Pharmacopœia.

A few words may now be added in regard to the actual preparation or compounding of ointments, a feature which continually requires the attention of the physician, if he would have success in the treatment of skin diseases. It is desirable for the physician to frequently inspect the ointments or other preparations which are being employed, and to test them by smelling, feeling, rubbing on the skin, etc.

More harm is commonly done by too strong ointments than is usually supposed. The skin is a sensitive and irritable organ, and more often wants to be treated considerably and soothed into good action, than it does to be stimulated and irritated. It is well to begin with a mild preparation, increasing the strength as the circumstances seem to demand. It is also well to remember that the average patient, who has not heretofore been instructed, or who has not had special experience, knows nothing in regard to the best mode of the application of an ointment, and if the highest degree of success is to attend the use of any particular remedy, it must be only by its proper employment. Careful directions should, therefore, always be given to patients exactly how to apply ointments. Where it is desired to keep a part continually under the effect of an ointment, it should be soaked in it, if it were possible, as completely as though the part were immersed in a very large mass of the same; but as this is not possible, we have recourse to lint, and the ointment, which should always have considerable body, is spread in a very thick layer on the woolly side of the lint, and then firmly bound on the part.

An excellent illustration of the necessity for minute directions in regard to all these data, is found in connection with eczema of the scrotum. When treated carelessly, or when the patient merely smears on an ointment, the disease will prove most distressing and rebellious; but when, on the other hand, very minute directions are given in regard to the sudden and brief application of hot water once daily, at bedtime, and when the part is quickly dried and enclosed with a piece of lint spread with the tar and zinc ointment previously alluded to, and covered by a suspensory bandage, the patient has complete relief, and with proper accompanying treatment can surely be cured, and that with reasonable speed.

The demand in dermatology is not so much for new drugs, applications, or methods of treatment, as it is for the diffused knowledge of what is already known to be of service, and the faithful carrying out of methods which experience and observation have proved to be useful.

#### ANTISEPTIC TREATMENT OF TYPHOID FEVER.<sup>2</sup>

In a lecture on this subject at King's College Hospital, Dr. Yeo has called attention to the progress that the idea of an antiseptic treatment of typhoid fever is making amongst physicians in all parts of the world. He is unwilling, in the present stage of our knowledge, to put too much stress upon any particular manner of carrying out this idea, as we have probably not yet arrived at the very best means for doing so. What he says about the idea of the application of anti-

<sup>2</sup> Lancet, No. 3529, 1891.

sepsis in typhoid fever by various practitioners, is of interest.

Professor Petresco, of Bucharest, has borne valuable testimony to the efficacy of naphthol; he had previously experimented with carbolic acid, salicylic acid, turpentine, benzoic acid, kairin, calomet, corrosive sublimate, and boric acid, without any very favorable results. He then tried a saturated solution of sulphide of carbon, with which he was much better pleased, and lastly he tried naphthol, fifteen grains three times a day, and had results more favorable than with any other remedy; the rate of mortality was reduced, and the course of the disease favorably modified. Many physicians have recorded their approval of an initial laxative, and no doubt it is well, if there be no diarrhoea, to begin with one; there is then less hesitation in keeping the bowels quiet afterward. Indeed, it has been said that "purgation and antiseptics are, to some extent, interchangeable terms."

An aperient expels the poisonous ptomaines and other decomposing substances from the intestinal canal, and, if given in the early stages, may actually prevent subsequent serious diarrhoea. But the use of aperients, to be perfectly safe, must be limited to the first ten or twelve days of the fever, the great risk attending their use in the later stages is the possibility of deep ulceration in the ileum, and in that case an aperient may mean the difference between life and death to the patient. At that period of the disease intestinal antiseptics can only be safely secured by the use of intestinal antiseptics.

#### HYDROCHLORATE OF PHENOCOLL, A NEW ANTIPYRETIC AND ANTIRHEUMATIC.<sup>3</sup>

This substance appears in the form of a white powder, soluble in water. It is a compound of phenetidine, and seems to be similar in action to antipyrin. Fifteen grains of phenocoll reduces the temperature about as much as would be accomplished by twenty-two to thirty grains of antipyrin or about fifteen of phenacetin. It has analgesic properties in doses of seven to fifteen grains.

#### PIPERAZIN.<sup>4</sup>

This substance has the property of dissolving a large proportion of uric acid. One part of the urate of this substance is soluble in about fifty parts of water. Urates of lithia requires 368 parts of water to dissolve it; the piperazin salt is, therefore, seven times more soluble than the lithia salt. Piperazin is not toxic, and appears to have advantages over other substances which may be used to act as solvents for uric acid. It seems to be worthy of trial in suitable cases.

#### METHODS FOR THE ADMINISTRATION OF AMYLHYDRATE.<sup>5</sup>

A teaspoonful of amylhydrate may be taken at night in a small glass of beer. It should be stirred for seven minutes to be sure of solution, or, of the following, one-half may be taken at night:

R Hydrate of amyl . . . . .	3 ℥.
Water . . . . .	3 ℥.
Orange flower water . . . . .	3 ℥.
Syrup of bitter orange . . . . .	3 ℥. M.

It is necessary to remember that amylhydrate dissolves slowly in water.

#### OXYGEN AS A DISTINCT REMEDY FOR DISEASE, AND A LIFE-SAVING AGENT IN EXTREME CASES.<sup>6</sup>

On this subject Dr. A. W. Catlin contributes an article to the *Medical Record*, 1891, No. 1086, and cites cases where oxygen has been used with advantage. Primarily, and for a long time exclusively, this agent has been recommended in lung difficulties—more especially to relieve dyspnoea and cyanotic conditions following in the train of pneumonia, where a large amount of lung structure is involved; another way of stating the fact that its use was deferred until the disease was far advanced, the strength exhausted, and the recuperative powers in abeyance—in other words, a last resort, as a palliative, but not as a curative. Fortunately, however, for our patients, another view is now taken of this life-saving agent, and to-day we recognize the fact that if we can, with a limited lung capacity in acute disease, pass more or less continuously the same quantum of oxygen into the blood that is normally required when no disease is present, we practically lift our patients to the plane of health, so far as functional activity is concerned, and give them a hundredfold more strength to battle with than before.

Dr. Catlin desires to show that oxygen is the most sure and satisfactory stimulant we have; that by being exhibited through the lungs and not by the stomach, its entrance into the circulation is much more certain and immediate; that its effect, felt primarily upon the heart, is almost as quickly seen at the nerve centres and in the digestive organs; that it is pre-eminently the remedy for profound shock, either from hemorrhage or nervous drain, where vitality is at too low an ebb to take up the intricate history of assimilation and repair.

To get the best results the remedy must be administered at first freely and continuously, especially in those cases of profound shock where the depleted centres of life must have this true stimulation offered unremittently. The only indications for a suspension of its use is a condition at once recognized by the patient, namely, super-excitation and dizziness, and this limitation is rarely reached in these extreme cases where the inhalations are not as deep or prolonged as they are when the strength returns and the demand for the stimulant naturally begins to limit itself. In other words, the patient, once instructed in its use and conscious of its helpfulness, is the best guide in its administration and can be safely allowed to breathe it *ad libitum*. The fear is they will not get enough, not that they will get too much. This, of course, implies that the pure gas mixed with nitrogen, two parts of the former to one of the latter, is being used.

There are many conditions under which oxygen can be exhibited always with relief, even if the nature of the case is necessarily fatal. It is no small thing to say that it relieves needless suffering.

The objection so often raised to it as a cumbersome remedy, not easily obtained on short notice, no longer holds, for depots are established in all our large cities.

#### DEATH AFTER SALOL.<sup>7</sup>

Salol is usually considered a tolerably innocuous drug, but there are not wanting clinical observations which tend to show that, under certain circumstances at least, it may be followed by dire results. Thus a

<sup>3</sup> Deutsche, med. Wochenschr., No. 15, 1891.

<sup>4</sup> Berlin Klinische, Wochenschr., No. 11, 1891.

<sup>5</sup> Nouveau Remède, No. 2, 1891.

<sup>6</sup> Medical Record, No. 1086, 1891.

<sup>7</sup> Lancet, May 23, 1891.

case was some time ago reported by Aufrecht and Behm, in which death followed its use in acute endocarditis, and more recently Dr. Chlapowski has published in a Bohemian medical journal an account of a case in which a similar fatal result followed a fifteen-grain dose ordered for a patient who was suffering from severe gastric symptoms, and who was being examined by Ewald's method. After taking the salol the patient became restless and unconscious, the pupils dilated, the pulse became irregular, there was constant vomiting, the urine became dark and contained salicylic acid. Death occurred twelve days later. At the autopsy there were found gastritis and hemorrhagic enteritis, a gastric ulcer cicatrized at the cardiac end, chronic endometritis and cyst of the ovary. No doubt was entertained that the salol had caused the symptoms of poisoning.

[In such cases the early use of the soluble sulphates such as Glauber's salt should not be omitted. — REP.]

(To be continued.)

## Reports of Societies.

### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING May 9, 1891.

DR. WALTER L. BERRAGE read, by invitation, a paper on

#### THE APOSTOLI METHOD OF TREATMENT, ITS TECHNIQUE.<sup>1</sup>

DR. BLAKE was interested to know that the electrical outfit could be obtained at such a reasonable price. He had supposed the cost was many times as great.

DR. BERRAGE replied that the low price was due to the fact that all the apparatus is now made in this country.

DR. WORCESTER asked as to the possibility of tapping the electric lines which now abound everywhere.

DR. BERRAGE said that experiments have been made in this direction, but thus far no rheostat had been made which could with safety control the powerful currents used for the arc light.

DR. HAVEN suggested that the Edison incandescent light wires with a lower power had been used.

DR. O. K. NEWELL, present by invitation, then made some very interesting remarks on

#### CYSTOSCOPY AND LITHOLOPAXY IN THE FEMALE,

and showed the various instruments used for these purposes, many of them being his own invention, and described in papers recently published by him.

In answer to questions, he said that only two cases of stone in the bladder in very young children had been reported in this country, one by Dr. Beach, in a child of three years, the other, a case of his own, in a child of eighteen months. The largest number of these cases was reported from India. In women, stone is very rare, and is often due to the presence of some foreign body introduced through the urethra.

DR. HAVEN spoke of a girl he had treated for incontinence of urine at the City Hospital, where the bladder was much contracted, holding at first only one and a half ounces. After several months' treatment

by dilatation with water, the capacity of the bladder increased to sixteen ounces, and the patient was then able to hold her urine all night. She then unfortunately stopped coming, and he does not know the subsequent history.

DR. STRONG said he had used the Skene endoscope after dilating the urethra with vulcanized rubber dilators. The view is unsatisfactory, and must be much inferior to that obtained by Dr. Newell's cystoscope. He has had several cases of contracted bladder, some of which he reported before this Society last year, and he has always found the treatment to be a long one, and that the patient would often become tired and stop coming as soon as she began to improve.

DR. BAKER said that in the chronic cases in the male where the bladder is much thickened and contracted, treatment is needed for a very long time, but in the ordinary cases seen in the female, he thought that the bladder could be gradually distended to its normal capacity within three months. After the closure of vesico-vaginal fistulas the bladder is very small, but he has been surprised with the readiness with which it can be dilated, and he has found that the cure was permanent and satisfactory. This condition of contracted bladder is, he believes, often found in cases of onanism due to frequent micturition, cases where it is best to avoid local treatment.

DR. BLAKE said he had seen a large number of cases of incontinence of urine in the unmarried about twenty-five years of age, where various forms of treatment — mental, moral and drug — he had often found to be unsuccessful.

Cases due to cystitis he thought were much less resistant to treatment, and he has recently found that the application once or twice daily of a two per cent. nitrate of silver solution gives the most relief.

DR. HAVEN had found a retroverted uterus in nearly all cases of onanism referred to by Dr. Baker.

DR. HAVEN reported

#### A CASE OF PRIMARY CARCINOMA OF THE VAGINA.

DR. BAKER remembered three cases of this form of disease: one reported by Dr. Bumstead, of New York, another case where the disease appeared on the posterior vaginal wall directly opposite a laceration of the cervix from which came a discharge, and a third case where the disease began lower down in the vagina. He thought that surfaces abraded by maceration from a decomposing discharge might very well, in old anemic women, be the starting-point for malignant disease. Hence the great importance in these cases of local cleanliness and tonics. With Dr. Forster he had seen a case of sarcoma of the vagina.

DR. A. WORCESTER had recently under his charge a woman, twenty years of age, who suffered from antiversión of the uterus. On the posterior vaginal wall two-thirds of the way from the vulva he discovered a small, bluish mass, which grew irregular and quadrupled in size in the course of a year. A snipping showed it to be sarcoma. The patient was operated on, but did not survive.

DR. BLAKE said that the case reported by Dr. Haven was sent into his service at the City Hospital. Examined under ether, the uterus was found to be small and rudimentary, wholly free from the disease. Within a few days another case had entered his service with undoubted carcinoma of the vagina, which contained spongy masses the size of a silver dollar,

showing great tendency to hæmorrhage; neither vulva nor uterus were involved.

DR. STRONG reported

A CASE OF CANCER OF THE OVARY,<sup>2</sup>

and showed the specimen.

DR. BAKER showed the new needle-holder of Dr. Burrage, which has been described and figured by the inventor in the *Boston Medical and Surgical Journal*. He considered it without qualification the best needle-holder he had ever used.

DR. NEWELL said that Billroth sews with a needle-holder very much of the same pattern.

DR. HAVEN said that the objection to aluminium for instruments was that this metal is easily dented and scratched.

DR. STRONG then spoke of the modification of Alexander's operation by Dr. Kellog, of Battle Creek. With Dr. Blake he had recently had the pleasure of seeing Dr. Kellog operate. He cuts down onto the inguinal canal instead of onto the ring, hooks in two blunt strabismus hooks, and pulls up the ligament, which is the more easily done at this point as there is more substance to it than at the ring. With a blunt aneurism needle a suture tied to a loop of the ligament is passed around outside of the conjoined tendon, thus shortening it by a double loop. In one case the operation was easily done under cocaine.

The criticism Dr. Strong would make is that he should feel doubtful of the efficacy of the single catgut stitch to keep the ligament in a new place so unnatural to it.

DR. BLAKE said that Dr. Kellog claimed for his modification, that it made the operation a trivial one and did not interfere with the blood-supply, and there was hence less danger of failure. Moreover the ligament was acted on where it is large and round, and where it would therefore be less liable to break.

DR. HAVEN said that he believed that a slight inflammation in the canal, stirred up by the operation, was a good thing, as it served to hold the ligament in place.

DR. STRONG agreed with this, and said that he had had only two cases where the operation failed to accomplish the purpose. In one of these, at a subsequent ovariectomy, he had found the ligament broken off at the uterine end, and in a second case the uterine ends were stretched, but at the ring the ligament held firmly. He emphasized the importance of pulling out considerable ligament.

DR. HARRINGTON said that he now made but one incision through which to find both ligaments. The advantage of this was a saving of time, a diminution in the amount of bleeding, more room and less wounded surface to heal. The incision made extends from the spine of the pubes on one side, with a downward curve, to the other spine. He believed in using the greatest possible aseptic precaution and in sewing up the wound without drainage.

At the annual meeting of the New York State Medical Association, held in New York on October 28th to 30th, the J. G. Orton Prize of \$100 for the best short, popular essay on some subject connected with practical sanitation was awarded to Dr. Howard Van Rensselaer, of Albany, for an essay on "Impure Air, and the Ventilation of Private Dwellings."

AMERICAN GYNECOLOGICAL SOCIETY.

SIXTEENTH ANNUAL MEETING HELD AT WASHINGTON, SEPT. 22-24, 1891.

THE PRESIDENT, DR. A. REEVES JACKSON, of Chicago, called the meeting to order, and introduced DR. JOSEPH TABER JOHNSON, of Washington, who delivered the

ADDRESS OF WELCOME.

The first scientific paper was read by DR. J. C. REEVE, of Dayton, O., entitled,

ADVANTAGES OF MIXED NARCOSIS IN GYNECOLOGICAL SURGERY.

The author classified the peculiar features attached to gynecological operations in general, which demand a profound abolition of sensation and maintenance of this condition, as follows: (1) The length of time required for many operations. (2) The necessity for absolute quiet of the patient. (3) The great sensitiveness of the parts involved in certain plastic operations. (4) A profound impression upon the sympathetic nervous system, as when the hand is passed into the abdominal cavity, or a large tumor suddenly raised from it. (5) The dependence of the success of the operation, and even the safety of the patient, upon the absence of vomiting.

He claimed that by the combination of narcotics with anesthetics the ordinary anæsthetic condition could be made more profound and be more steadily maintained. The method consisted in the administration of a hypodermic injection of morphia and atropia some little time before the anæsthetic. The process originated with Nussbaum in 1863, followed by Bernard in 1864, and Harley in 1869, who taught the value of atropia as a cardiac stimulant, especially where chloroform or any other cardiac paralyzing agent was used. The author has used the "mixed narcosis" in all major operations for the past twenty years, in the following proportions: sulphate of morphia,  $\frac{1}{16}$  to  $\frac{1}{4}$  gr.; sulphate of atropia,  $\frac{1}{16}$  to  $\frac{1}{32}$  gr.; dose six to eight minims of solution of sixteen grains of morphia and half a grain of atropia to the fluid ounce; the anæsthetic used was the A. C. E. mixture (alcohol one part, chloroform two parts, ether three parts).

By this method the emotional excitement of the patient is allayed, the anæsthesia is effected with great rapidity, the sense of suffocation attending the inhalation of ether is absent, the anæsthesia is steadily maintained, and the patient is absolutely quiet. A period of quiet rest and freedom from pain succeeds the operation; vomiting, sometimes so dangerous after operations, is lessened.

In regard to the safety of this method, he could find reports of but three deaths under it, in none of which was death typical of that from anæsthetics, that is, by sudden failure of cardiac action or of respiration, or of both simultaneously. In one, a grain of acetate of morphia was given subcutaneously before chloroform, (an amount of narcotic hazardous in itself), and death was by narcotism. In his own experience, he had never had an accident of any kind having used it for all kinds of operations, on patients of all conditions and ages except young children. The contrast in the same patient between the simple and mixed narcosis is strikingly in favor of the latter.

He believed this method less dangerous than the

<sup>2</sup> See page 564 of the Journal.

ordinary anaesthesia for the following reasons: (1) Absence of emotion, the presence of which was often the cause of fatal accident. (2) The smaller quantity of anaesthetic required, especially advantageous in prolonged operations. (3) The shortened and diminished violence of the struggling stage. (4) The stimulating influence of atropia upon cardiac action and respiration. (5) The effect of morphia in lessening the liability to reflex inhibition of the heart. (6) Experiments on animals.

DR. J. M. BALDY, of Philadelphia, had used the mixed narcosis with ether as the anaesthetic; but where he could have full personal control of the preparation of the patient for operation, he had not found any essential difference between the two methods. He believed that most of the struggling of the patient during the anaesthesia was due to gastro-intestinal irritation, and where he had cleared out the gastro-intestinal tract prior to the operation by freely purging the patient, the patient had remained just as passive as in the cases where he had used the mixed narcosis. He had seldom seen vomiting after ether narcosis.

DR. JOHN BYRNE, of Brooklyn, had used the mixed narcosis for many years with ether as the anaesthetic, and believed that all the good effects claimed by the author of the paper could be obtained as well when ether was used as the anaesthetic as when the A. C. E. mixture was used.

DR. HENRY C. COE, of New York, read a paper on ACCIDENTAL HÆMORRHAGE OCCURRING DURING THE FIRST STAGE OF LABOR AT TERM.

Since Dr. Goodell's paper on this subject, some twenty years ago, there has been very little added to our information concerning it. It was not the writer's purpose to discuss the entire subject of accidental hæmorrhage in the gravid womb, but simply that form which occurs during labor, which is not only the more infrequent but the more fatal form, being rarely of traumatic origin. Five-sixths of the cases have been due to injury and have occurred before term. The writer recited a fatal case in his practice.

He considered the etiology of these cases obscure, traumatism being the most frequent factor before labor. The predisposing causes were hæmorrhagic diathesis, general febrile affections, renal troubles, death of fetus, hydramnios, diseases of the placenta. In twenty per cent. of the cases, irregular uterine contractions have been noticed. In a certain number of cases the cause was undoubtedly due to abnormal shortness or twisting of the cord. The accident could not be ascribed to a single etiological factor in the non-traumatic case; there being usually a combination of several, as irregular and imperfect uterine contractions, with extensive fatty degeneration of the placenta. What combination may lead to hæmorrhage it is difficult to state.

The symptoms are divided into two sets, initial and final, the majority of writers believing that only the latter are reliable, and are recognized too late to remedy. The writer considers accidental hæmorrhage diagnosable at its inception by watching the initial symptoms, such as irregular and feeble labor pains.

Continuous pain in the lower part of the abdomen gradually growing worse and assuming a bursting character, is one of the symptoms. Nothing abnormal may be found on external palpation, but auscultation of the fetal heart shows it is feeble and irregular, an

important symptom, indicating some serious disturbing influence to the fetus, not accounted for by ordinary prolonged labor. The case may be mistaken for one of a simple uterine inertia, the patient being able to sit up and walk about, her pulse not being affected. All these symptoms should lead the attendant to suspect a possible commencing hæmorrhage. External bleeding would confirm the diagnosis: this symptom has been absent in three-fourths of the cases reported. The signs of internal hæmorrhage now appear, and with the arrest of the labor the patient grows weaker and may die at any moment, or the membranes may rupture, and she may be delivered and afterwards die from post-partum hæmorrhage, or shock. The writer believed that death was not unfrequently due to hyperdistention of the uterus rather than to actual loss of blood.

Accidental hæmorrhage may be mistaken for a severe attack of colic, but this error could hardly be made during the labor, if the condition of the uterus was carefully observed. It is distinguished from rupture of the uterus by the fact that the latter accident occurs during the progress of active pains usually before the rupture of the membranes, and is followed by a diminution in the size of the uterus, recession of the presenting part, and the sudden onset of symptoms of internal hæmorrhage.

In order to save the mother and child, or even the mother alone, there must be a combination of favorable circumstances — skilled and prompt attendant, unusual resistance to shock in the patient, and after delivery proper uterine contractions.

The writer's plan of treatment was, as soon as the accident was recognized to vigorously stimulate the patient by mouth, rectum, and hypodermically, while sending for aid. Under complete anaesthesia the os should be carefully dilated manually, Barnes's bags only being employed when the os was rigid and the patient's condition was such that a certain amount of delay could be safely practiced; the membranes should be preserved intact; then version should be performed with unusual care to avoid rough manipulation. At this stage ergot should be freely administered hypodermically. There should be a short delay before extraction in order to give the uterus time to recover its tone. If the head is arrested by the poorly dilated os, it should be perforated, instead of wasting time in trying to drag it out. The most important step is the prevention of post-partum hæmorrhage. Without delay the hand should be introduced into the uterus, the placenta and clots removed and the cavity tamponed with iodoform gauze.

DR. CHARLES JEWETT referred to the friability of the vessels and the conditions which favor easy separation of the placenta, also undue uterine contractions, as factors in the etiology of these cases of severe hæmorrhage. He related a case in which hæmorrhage was due to undue uterine contractions, in a malarial patient, due to twenty-grain doses of quinine three times a day. Fatal damage is often done before the symptoms are sufficiently developed to make a positive diagnosis, but there are certain premonitory signs, such as persistent pain in the abdomen during the early labor, which should keep the obstetrician on the alert, and suggest the possibility of this form of hæmorrhage. He agreed with the writer that the membranes should not be ruptured until the cervix was fully dilated. Hæmorrhage may be controlled by

the abdominal bandage before the membranes are ruptured. Delivery may be accelerated after the first stage of labor is completed, but too precipitate interference at a time when the patient is in profound condition of shock from hæmorrhage, should be avoided. He had had good results with the intra-uterine tampon of sterilized gauze.

DR. R. A. MURRAY emphasized the difference in treatment before and after the os was dilated. In one case, where enlargement of the abdomen, doughy feeling of the uterine tumor, and very severe pain indicated hæmorrhage, he tamponed the uterus, compressed the arteries of the lower and upper extremities, and elevated the feet, thus keeping the brain alive, and let the uterine tumor alone; at the same time giving hypodermic injection of stimulants. Shortly afterward the os dilated, pains came on, uterus contracted, waters ruptured, child delivered, and he turned out nearly a kitchen basin full of clots. In another case where the os was dilated, he ruptured the membranes, kept the brain alive in the same manner, and delivered with forceps. In both cases the shock was most profound, fatty and calcareous placenta was the cause of hæmorrhage; external hæmorrhage was not more than a cupful when the shock was most profound. He believed that keeping the brain alive in the above manner was the determining element in his success in saving both patients. He believed in tamponing the uterus, or if the membranes had not ruptured, he would tampon the vagina, which would cause the cervix to dilate, prevent hæmorrhage and give a barrier to press against if compression of the uterus has to be made.

DR. HENRY D. FRY thought Porro's operation would be a justifiable procedure in cases of violent hæmorrhage where the cervix was not dilated. He referred to a successful case by this method which was narrated by Dr. William Smiley, in the opening address before the Obstetric Section of the British Medical Association last July.

DR. T. A. REAMY, out of a series of 3,000 obstetric cases seen before and during labor, had only seen one case of accidental concealed ante-partum hæmorrhage sufficiently severe to be worthy of report. This case he saw in consultation, and found the patient in collapse. He delivered immediately with forceps, the head being on the perineum, and turned out two very large clots, one nearly as large as the fetal head. The most peculiar features were extreme thinness of the uterine walls, and the immense amount of coagulated blood. The woman died before the digital examination was finished.

DR. EDWARD REYNOLDS referred to Dr. Goodell's cases, many of which were marked early by a tumor formed of effused blood behind the placenta, indicated by the circle-shaped edge and peculiar doughy feeling. While this diagnostic sign cannot be depended on in all cases, it is so important when it does occur that it should be emphasized. If the accident is detected early he would check the hæmorrhage by manual dilatation of the os and complete evacuation of the uterus, which reduces the distension, and tends to lessen the shock from this source. In two cases where the patient was in labor and almost moribund from hæmorrhage, he had introduced a strong styptic, such as Monsel's solution, into the uterus, with instant arrest of hæmorrhage and no bad after-effects.

DR. A. J. C. SKENE considered it rather dangerous teaching to recommend Porro's operation in these

cases. The mortality of this operation under much more favorable conditions would not commend it to his judgment.

DR. T. ADAMS EMMET suggested inversion of the uterus and control of the hæmorrhage by ligatures.

DR. COE in closing the discussion, said he thought on general principles the tampon should be banished from gynecological and obstetric surgery. It was very apt to shut up discharges which should come away. An important point in diagnosis which he omitted to mention, was the introducing of the hand into the vagina, and pushing up the head of the fœtus, and if there was a concealed hæmorrhage it would escape, and the diagnosis would be cleared up at once.

DR. JOS. E. JANVRIEN, of New York, read a paper entitled,

#### A CLINICAL STUDY OF PRIMARY CARCINOMATOUS AND SARCOMATOUS NEOPLASMS BETWEEN THE FOLDS OF THE BROAD LIGAMENTS, WITH A REPORT OF CASES.

Malignant neoplasm other than those of the ovaries sometimes do occur *primarily* between the folds of the broad ligaments.

The author gave the history of three cases, one a sarcoma of the Fallopian tube, the second a primary carcinoma of the parovarium, and the third, cystic angio-sarcoma of the left broad ligament, and lipoma of the right, with dilated tubes.

The history of all three of the cases pointed plainly to the primary development of malignant growths.—two sarcomatous, and one carcinomatous, within the folds of the broad ligament.

To the author's knowledge, Case No. 2 is the only recorded case of an adenoid hypertrophy in the parovarium undergoing degeneration and transition to a carcinoma; he also believes that there is no other recorded case of a primary carcinomatous development within the folds of the broad ligament, aside from those which develop in the ovary proper. Improper treatment may act as determining cause in giving rise to malignant growths. The first case had a clear history of trauma. The patient was treated by a homeopathic physician, who gave her repeated injections of ergotine par-vaginum into a supposed uterine fibroid. The second case had been treated by galvanism, for a sub-peritoneal fibroid.

DR. A. W. JOHNSTONE believed that cancers in the parovarium extending into the broad ligament were more common than was generally supposed. This organ is a remnant of fetal life whose functional activity is at an end, having very little nerve or vascular supply. He had found true cancer in the ovary only twice, but in each case there was beginning carcinoma in both broad ligaments. Schirrus cancer was most marked in the hilum of the ovary. He believed in many cases of so-called simple ovaritis there was cancer present at the time of operation, for in six months or a year afterwards some of these cases develop cancer and death follows. If operators would examine their pedicles more carefully cancer nodules might be found at the time of operation.

DR. A. P. DUDLEY agreed with the author that where there is existing pelvic disease the use of electricity or violent injections into the pelvis will cause malignant disease to spring up in the broad ligaments. He had seen one such case treated by Dr. Apostoli, and several others in New York.

DR. A. F. KING agreed, with Dr. Johnstone, that

these cancers were the result of defective nerve-supply and consequent defective government of nutrition of the tissues—a growth of cells without government. Excessive doses of electricity no doubt paralyze or destroy the governing nerves, and the tissues are cut off from their natural nutrition. Uterine cancer after the menopause might be accounted for on the same grounds, the functional activity of the uterus has ceased, and if the cells go on growing they have no nerve government.

DR. JANVRIK, in closing the discussion, said if laparotomists would examine their specimens more carefully under the microscope they might in many cases find the beginning of cancer. He believes from a long experience that nearly all cases of cancer of the uterus and its adnexa are the result of injuries. He was not a believer in the hereditary tendency to cancer to any extent.

DR. ROBERT P. HARRIS, of Philadelphia, presented a paper on

#### THE PRESENT AND IMPROVING STATUS OF CÆSAREAN SURGERY,

which was read by DR. WM. H. PARISH, of Philadelphia.

The author compared the Porro-Cæsarean operation and the new or improved Cæsarean operation (sometimes spoken of as Sanger's operation), the latter of which he believed was more frequently performed and with a greater degree of general success.

He regards the new Cæsarean operation as one, *per se*, of a moderate degree of risk, in the hands of a skilful operator, and with the woman in good condition. His personal experience covers thirteen cases, with only two deaths.

The greatest obstacle to the success of Cæsarean surgery, more especially in this country, is due to the fact that cases are not brought to the obstetric surgeon until the risk of using the knife has been greatly increased by the effects of labor and attempts at delivery. Out of the eighteen true Porro cases in the United States, in eight the fœtuses were already dead, and some of them commencing to decompose before the knife was resorted to. If we look over the records of the most successful work in Europe, we shall find how intimate has been the connection between the living fœtus and the subsequently saved mother. This being the case, the saving of the woman must begin with the management under the obstetrician first consulted upon her condition.

If he should happen to know the requirements for Cæsarean success the case will probably be so managed as to attain it, but if, on the contrary, he should prove to be one of the large number of half-trained obstetricians, that are the curse of poor parturient women in our large cities, the result may be decidedly adverse before he is fully aware of the necessities of the case. Perhaps the requirements of a medical education in Austria and Germany may be one of the reasons for the better results in Cæsarean surgery in their maternity hospitals, to which cases are directed by young obstetricians practising in the homes of the poor.

By a careful observance of the following, the results would be much improved: make the operation one of election; perform it either before labor, or early in its progress; urge antiseptic treatment of cases; cease experimenting; use Es-march's elastic tubing, or strong manual compression, to control uterine hemorrhage;

when the uterus contains a dead fœtus evacuate it without the abdomen, especially if there is septic fluid and gas present.

Wash out the abdomen with distilled water (105° to 110° F.) where blood has entered or in case of threatened collapse; collar the stump, by sewing the cervical to the abdominal peritoneum so as to shut the peritoneal cavity against the entrance of septic fluid around the stump; isolate the stump from the abdominal skin by prepared packing; employment of cul-de-sac for abdominal drainage.

DR. H. MARION SIMS, of New York, related a

#### UNIQUE CASE OF MULTIPLE NEURO-LIPOMATA FOLLOWING LAPAROTOMY.

The patient, a strong girl of eighteen years of age, was married in 1884. She returned from her wedding trip a week later, a complete wreck. Vaginismus was the cause of this sudden change. I excised the hymen, and in a short time her nervous symptoms disappeared, and she was discharged as cured. About eight months after that I was hastily summoned to her to find her in violent convulsions, and in about the seventh month of pregnancy. Patient complained of violent pain in region of left ovary. Examination revealed an enlarged cystic ovary jammed tightly between the uterus and abdominal wall on the left side. Pressure against the ovary caused excruciating pain. By the use of nitrite of amyl, by inhalation, the patient was made tolerably comfortable up to the time of labor, when I thought she would be free from her hystero-epileptic attacks, when the pressure of the gravid uterus was removed from the ovary. Such was not the case, however, and shortly after her delivery, which was uneventful, the attacks came on with renewed violence, the other ovary also now showing signs of cystic degeneration. Her condition had now become so distressing that laparotomy was decided upon and performed, removing two very much diseased ovaries and tubes. The convulsions entirely disappeared, and she made a good recovery; and I supposed that was the last I should ever see of her.

About six months after this I was again hurriedly summoned, to find my patient in bed suffering intense pain in the abdominal wall about an inch below and to the right of the umbilicus, over an area not larger than a five-cent piece; the lightest touch with the fingertip caused the most acute pain. After considerable difficulty I succeeded in freezing the spot, made an incision, and removed from the surrounding fat a little tumor which felt like a large duck-shot embedded under the skin. After removing it, the finger could be pushed into every corner of the wound without causing any pain whatever. On the second day I removed a nest of these growths from the abdominal wall to the left of the umbilicus. The incision was packed with antiseptic gauze. Microscopical examination showed them to consist of hardened fat and connective tissue, with a tiny nerve filament running through the whole and seemingly tightly in the grasp of the tumor itself.

This condition of recurrence continued for more than two years, and I removed these growths from every part of the abdomen, as high up as the seventh rib, there being a cessation of pain after each removal. All kinds of medication were tried, electricity and constitutional treatment, with absolutely no effect.

At the end of the second year the growths showed evidence of disappearing, and in the thirtieth month

from the first appearance of the growths, I made my last incision removing a group of them from the upper part of the left thigh. There were twenty-eight incisions in all, two on the thigh and two on the forearm, the remaining twenty-four on the abdomen.

She has now enjoyed good health for three years, which I think is sufficient time to justify me in pronouncing the case as cured. Many gynecologists and neurologists saw the case; and all agreed that it was the only case of the kind they had ever seen, nor can I find any literature on the subject whatever.

DR. GARRIGUES asked if closing the incisions with sutures was contra-indicated.

DR. SIMS replied that the first incision had been closed with sutures, but there was so much fatty exudation, that all the subsequent ones had been packed with gauze and allowed to granulate.

(To be continued.)

## Recent Literature.

*Mental Suggestion.* By DR. J. OCHOROWICZ. With a Preface by CHARLES RICHET. Translated by J. FITZGERALD, M.A. 8vo. pp. 369. The Humboldt Library of Science, Nos. 151-158. New York: The Humboldt Publishing Co. 1891.

For a long time men have believed that ideas may be conveyed from one mind to another independently of any communication through the senses. To a student of the new physiological psychology such a notion presents, *a priori*, many difficulties. The careful scientific study of the nervous system, based on certain well-established facts, cannot admit that cortical cells can be stimulated without some centripetal irritation,—that is, an irritation conveyed from the outer world, a true sensory impression, or irritation from some other group of cells in activity, an associated impression. If, now, it be established that these cortical cells can be stimulated by the action of a similar group of cells in another brain, every communication through the five senses being excluded, one of two things must follow: either there is another centripetal path excitable by unknown agencies, a sixth sense, or the whole scheme of the functions of the nervous system must be abandoned. The scientific man will, therefore, be sceptical as to thought transference until a mass of indisputable evidence has been brought forward. Such a presentation of facts will require years of the most accurate observation.

The doctrine of thought transference was brought forward and given a certain cachet of respectability by the Society for Psychical Research. To many their conclusions seemed hasty and their experiments indecisive; the patient research that does not publish until its conclusions are established was lacking, and when, later, the investigators were proved in one case to be the dupes of clever children, confidence in their subsequent discoveries received a severe blow. Independently of their researches others have investigated the problem, and one of the results of such investigations is before us.

The author admits that he has been a convert to the theory of thought transference, or "mental suggestion," for only one year. In his first chapters he gives a very full account of the sources of error which may arise in such investigations, which render the experi-

ments remarkable merely as showing unwonted activity in certain well-recognized mental processes of perception and association. Then he goes on to give certain remarkable experiments which apparently cannot be explained by any known mental processes, unless we admit thought transference, that is, unless we admit that one mind can act upon another, apart from any mutual processes of association excited by external causes, and apart from any communication through the five senses. Here scepticism becomes the safest ground. "When there is question of an experiment in mental suggestion, I put no trust in anybody but myself," he writes. In one case "I was myself deceived." If in one case, why not in others? If he trusts no one but himself, why should we trust him? His belief that there is a process of magnetization distinct from hypnotism is certainly doubted by the majority of the best students of hypnotism; his hypnoscope has met with little acceptance; and his experiments, remarkable as they are in the telling, must be received with doubt, until thought transference has won a surer footing than it now holds. It takes a longer period of gestation to bring forth a dogma that can successfully overturn existing beliefs.

The study of these phenomena seems in some way provocative of credulity. At any rate, in the second part, where the consideration of the views of other writers is undertaken, the apparent scientific scepticism with which the author begins his work is thrown to the winds. All manner of marvels are cited with an apparent acceptance. Clairvoyance, the transfer of disease from A to B, and then a further transfer from B to C, the production of intoxication in B from wine drunk by A, the suggestion that by thought transference we may communicate with one another at a distance as we do now by telephone (a great saving!), are all reckoned among the possibilities. If these things be true, then Bulwer's "Strange Story" and "House and the Brain" will be matters of daily experience, and the "Arabian Nights" will become realistic enough to please Mr. Howells himself.

The third part is devoted to the theories which explain thought transference. The hypothesis that the writer suggests is most complex, but he implies that in some way the physical, chemical and thermal changes in the transmitting brain may set up similar actions in the brain of the transmittée, which have some analogy with the current induced in a piece of iron by the passage of a current through another piece of iron at a distance,—a hypothesis, it is needless to say, which still demands the first substantiation of proof.

*The Neuroses of Development.* Being the Morison Lectures for 1890. By T. S. CLouston, M.D., F.R.C.P.E. With nine illustrations. 8vo. pp. viii, 138. Edinburgh: Oliver & Boyd. 1891.

"In the course of the growth and development of the brain there are liable to occur certain failures in the attainment of a working standard of nervous and nutritional health, and the resulting defects or diseases may properly be called 'Neuroses of Development.' They have a natural relationship to each other in that they are thus developmental; and for the ultimate aetiology of them all we have to look to heredity." Such is the introduction to a work necessarily from our present lack of knowledge "imperfect and fragmentary," but full of suggestions and of the utmost importance to the general practitioner. The period of

development, that is the period which the brain requires to reach maturity, is regarded by the author as twenty-five years, and in this period the great factors are age, onset of function, and heredity. The developmental defects are therefore classified as those of the formative and embryonic stage, those of the period of most rapid brain growth (from birth to seven years), those of the period of co-ordination of motion and emotion (from seven to thirteen), and those of puberty and adolescence. The functions of the nervous system vary in the period of their development so that we may see early functions perfectly developed while later functions are absent. These variations are demonstrated in cases of idiocy and imbecility. With a bad neurotic heredity, morphological defects are very common, and physical ugliness is a characteristic trait of the majority of the degenerate, idiots, insane, neurotic, criminals, and the "submerged tenth." One of the striking morphological defects is an alteration in the shape of the hard palate, the percentage of "typical" palates in the degenerate being only one-half that of the general population. The various developmental diseases are next considered in their relations to one another and to defective heredity — infantile paralysis, Friedreich's ataxia, rickets, chorea, hysteria, adolescent insanity, epilepsy, etc. The neuroses are regarded as more or less interchangeable in heredity, but the same departure tends to return. There are two tendencies in heredity, one to revert to the normal healthy type, the other for the variation to become accentuated, leading to extinction. "The possible factors in the heredity of neuroses are so complex and multiform that it must be one of the last branches of medicine to be fully elucidated." Heredity is regarded as the predisposing cause of all these neuroses and the sole cause of many. The writer, however, uses neuroses in rather a vague way; thus, he speaks of cerebral infantile paralysis being attended by other neuroses, — squint, talipes, aphasia, etc., — disturbances often due to the location of the lesion or to purely mechanical causes secondary to the nervous lesion that causes the paralysis. The lectures close with all-too-brief hints as to treatment, which might well be expanded into another chapter. "Fatness, self-control, orderliness, are the three most important qualities for them to aim at." We recommend every physician in general or family practice to study this work carefully. By so doing he can aid the great class of the degenerate whom he sees at the outset of their career, and do something toward the prevention of the neuroses.

*On the Medical and Surgical Uses of Electricity.* By GEORGE M. BEARD, A.M., M.D., and A. D. ROCKWELL, A.M., M.D. Eighth edition, with 213 illustrations. 8vo, pp. xxvii, 788. New York: Wm. Wood & Co. 1891.

In the present eighth edition of this well-known work many changes and additions have been made, and two new chapters, one on the dosage of electricity, the other on the physical and physiological activities of the induced current, have been added.

ISLEUSZA, of an epidemic type, appears to have re-kindled in different parts of the world, especially in Europe. It has recently been reported from several towns in England, France and Germany, and is very extensive in Russia.

### THE STUDY OF THE CRIMINAL.

MANY years ago there was published in America one of the most elaborate studies in the heredity of crime and pauperism that has ever been made, but, perhaps because it was premature, perhaps because the science of criminal anthropology was then in its infancy, it led to no further researches, and, since then, with the exception of a few admirable studies of the convolutions of the criminal brain, this country has made no important contributions to the study of the criminal. In 1884, in the preface to the third edition of "L'Uomo Delinquente," names from South America are cited, but none from the United States. Yet the work done in other countries had already reached enormous proportions. Italy, of course, continues to lead the world in both the quality and the quantity of her contributions; but international congresses have been held, new journals of criminal anthropology have been started. France, Germany and Russia have done much, and England, Spain, Portugal and South America are falling into line.

It is to Italy, however, that the student must first look for aid in the study. Lombroso, "il maestro di color ehe sanno," with a band of zealous pupils under him, is still working at Turin with unflagging zeal, weighing and measuring the criminal in the minutest detail. His *Archivio* is in its twelfth year, and the fourth edition of his epoch-making and monumental work, "L'Uomo Delinquente," is now appearing, and French, German and Russian translations of it have also been published. It is, perhaps, still a question how far all of Lombroso's hypotheses are to be accepted, but the enormous amount of material which he has collected renders one fact reasonably clear — a fact in which almost all workers agree, whatever be their lesser differences — that criminality is as much a form of nervous degeneracy as alcoholism, insanity, epilepsy, or other nervous affections. Lombroso claims that he found but one man with the physical stigmata of the born criminal who was not a criminal. This may not be an invariable rule. Giacomini has doubted Bene-

dikt's hypotheses that there was a peculiar arrangement of the convolutions in the criminal brain. We may hesitate in spite of Lombroso's name, before accepting his hypotheses as to the identity of criminality and moral insanity, the close relations between criminality, genius and masked epilepsy, or the atavistic character of crime. Nevertheless the man who attempts to deny this main thesis, that crime is a form of degeneration, can find few men who know aught of criminal anthropology to support him.

To the October number of the *Alienist and Neurologist*, Drs. Lydston and Talbot contribute an article which is noteworthy, not only on account of its intrinsic merit, but because it is one of the first contributions to the scientific study of the criminal to be made in this country. The paper is a condensation of a more elaborate study which is promised later. The histories of eighteen picked habitual criminals are given, presenting many marked types of physical degeneracy, and a study of nine crania, chiefly of criminals, is added. These skulls show most remarkable aberrant types, they have been carefully studied; and they show marked asymmetry and irregularity. The writers are of the opinion that the more pronounced criminal types in this country are to be seen in the imported criminals, that the results of evolution and atavistic tendencies are more marked in older countries. The striking features in criminal crania which they find are the tendency to brachycephalism, submicrocephaly, and the great frequency of cranial asymmetry.

It may be objected that Drs. Lydston and Talbot have studied extreme cases and have not examined large numbers of criminals for the purpose of getting average measurements. This is in part true, yet Amadei, De Paoli, Cougnet, Bono, Lombroso, Benedikt and many others have found these cranial anomalies, perhaps less marked, in examining large numbers of criminal crania. They are certainly a departure from the normal, much commoner in the criminal than in the healthy man. Dr. Lydston argues, with justice, that a distorted skull probably means a change in the capacity of the cranium, and that it undoubtedly has an effect upon the brain. A single anomaly is not, perhaps, pathological, but when we get many anomalies, in skull, jaw, eyes, nose, ears, teeth, limbs and trunk combined, it is a strong indication of physical degeneracy, and physical degeneracy is now known to go hand-in-hand with mental and moral degeneracy.

If the objection just given be urged, although unjustly, against Dr. Lydston's work, it cannot be urged against the study of the jaws and teeth in criminals made by Dr. Talbot. He has studied the jaws of 177 criminals. Of these nearly 64 per cent. (314 criminals) presented anomalies, large or small jaws, protruding jaws, high vaults, or V-shaped or saddle-shaped arches. Dr. Talbot does not agree with Lombroso in ascribing an exaggerated development pre-ninently to homicides, nor with Ferri in ascribing small jaws to pickpockets. Nevertheless the great amount of ab-

normality affords further proof of physical degeneracy.

It is to be hoped that further investigations may be undertaken on the criminal in this country. The new science of criminal anthropology is likely to meet with opposition in many quarters, especially among those who cling to the old dogmas of free will and human responsibility. Even in Italy, where jurists, like Garofalo, as well as physicians, are studying crime under its new aspects, the modern views are not recognized in the new penal code. Their object is still the same as the Mikado's, "to make the punishment fit the crime." The new science changes all that, and shows that we should make the punishment fit the criminal. The born criminal is a degenerate, with a "will" impaired by bad heredity and defective brain development; he is often no more responsible for his crime than the epileptic for his fits, the paranoiac for his acts, or the drunkard for his inebriety. If taken early, he may be educated into being a tolerably useful member of society. Ordinarily, as we find him in the prisons, he is chronic, and often incurable. Our prisons do nothing to cure him, but much may be done in proper institutions, like Elmira. In default of a cure detention is requisite, as with the insane, as a protection to society; but, as with the insane, the detention must be until he is cured, or, if his case be incurable, it must be for life, whether his "crime" be petty larceny or murder.

#### LAPAROTOMY FOR INTESTINAL PERFORATION IN TYPHOID FEVER.

DR. WELLER VAN HOOK, of Chicago, reports a successful case of laparotomy for intestinal perforation in typhoid fever with recovery, two cases followed by death, and then discusses the reasons and the indications for operating.<sup>1</sup> In the successful case, according to the report, the history pointed indubitably to the existence of typhoid fever; the mechanical explanation of a perforation was supplied by the fact that active peristalsis had been excited by an enema; the symptoms of anxiety, pain, and shock were typical; the objective symptoms noted were supplemented four hours after the accident by a rising temperature (106°) and an increasing pulse-rate (132), plus the typical signs of peritonitis, namely, tympanites, tension of the abdominal muscles, and tenderness upon pressure over the ileo-cæcal region.

The patient was supposed to be suffering from a relapse after three weeks of a first attack. The perforation occurred on the eighth day of this so-called relapse, and the operation was performed nine hours and a half after the occurrence of the accident. One ulcer, irregularly circular in form and about two millimetres in diameter, was found in the small intestine, and the opening closed with three longitudinal rows of interrupted Lembert sutures. The patient recovered perfectly; the symptoms of typhoid, running a

<sup>1</sup> Medical News, November 24, 1891, p. 591.

normal course by a typical defervescence, ended in two and one-half weeks.

After a general consideration of the diagnosis and treatment of perforation in typhoid fever, Dr. Van Hook reaches the following conclusions: (1) There is no rational treatment for perforation in the course of typhoid fever, except laparotomy. (2) The indication for laparotomy when perforation occurs in typhoid fever is imperative. (3) The only contra-indication is a moribund condition of the patient. (4) Collapse is often at least temporarily relieved by hot peritoneal flushing. (5) The stage of the fever is not to be considered as an indication or as a contra-indication for laparotomy. (6) The severity of the typhoid fever is alone not a contra-indication. (7) Early laparotomy offers the most hope. (8) The symptoms of peritonitis should not be awaited before operating. (9) In taking charge of all typhoid fever patients, it is the physician's duty to be ready, in case of perforation, to perform laparotomy. (10) The published statistics of laparotomy for this condition are strongly in favor of operation. (11) The technique, though not complicated, demands much thoughtfulness, acquired dexterity, great rapidity and thoroughness.

Dr. Van Hook himself acknowledges in this paper, that the diagnosis of intestinal perforation in typhoid fever may be very easy or very difficult, but it seems to us that in drawing up his conclusions he forgets part of what he had previously admitted. The difficulty of the diagnosis in some cases detracts from the force of the conclusions.

These conclusions differ somewhat from those reached by Fitz in a very thorough *résumé* of the whole literature of the subject, read before the Association of American Physicians at its last meeting, and published in full in this JOURNAL, October 1st and 8th,—a paper to which Dr. Van Hook makes no reference.

Dr. Fitz draws the following conclusions as the result of his study of the subject:

This complication is found in about one per cent. of all cases of typhoid fever, and is the cause of death in something more than six per cent. of the fatal cases. It rarely occurs in children, and is twice as frequent in man as in woman. It is present in the small intestine in more than four-fifths of the cases, and usually proves fatal during the first week after its occurrence. It takes place in mild or severe cases, and its symptoms may be absent or latent, gradual or severe.

Differences of opinion concerning its prognosis have existed for many years, and are based upon a lack of agreement as to the value of the symptoms. Though these are often called characteristic, they give evidence only of a peritonitis, general or circumscribed. This may, in typhoid fever, result from a variety of causes, and fatal perforation may occur without any symptoms suggesting its presence.

Most cases of recovery from symptoms of perforation of the bowel in typhoid fever, are those in which an attack of appendicitis is closest simulated, while the great majority of the fatal cases are those in which

other parts of the bowel than the appendix are perforated. It is probable that the appendix is more often inflamed and perforated in typhoid fever than has hitherto been suspected.

The prognosis of apparent perforation of the bowel, in typhoid fever, is to be regarded as the more favorable the more closely the symptoms and their course resemble those of an appendicitis.

In the treatment of this complication early laparotomy is reported to have been tried in ten cases, with but one successful result; while of twenty-seven cases of circumscribed peritonitis in typhoid fever, largely attributed to intestinal perforation, three recovered after incision, seventeen after resolution, and nine after the spontaneous discharge of pus.

It is recommended that immediate laparotomy be employed for the relief of suspected intestinal perforations in typhoid fever only in the milder cases of this disease. In all others evidence of a circumscribed peritonitis should be awaited, and may be expected in the course of a few days. Surgical relief of this condition should then be urged as soon as the patient's strength will warrant.

#### MEDICAL NOTES.

LEPROSY IN PARIS.—A ripple of excitement has arisen in Paris from a recently published report that there are a hundred cases of leprosy in the city, some of them in natives of the city, who have never been in infected countries. There will probably be an official investigation of the subject.

THE GERMAN PHARMACOPEIA, appears now under the title *Artzneibuch*. This seems to have been done under the influence of a widespread desire in Germany to perpetuate things essentially German, and to resist foreign innovations, especially in language. The standing committee of the *Artzneibuch* at its last session considered 1,603 new preparations, of which all but 42 were discarded.

WOUNDS FROM MODERN BULLETS.—In an Austrian periodical, says the *Lancet*, a regimental surgeon named Thurnwald makes an interesting comparison between the wounds caused by the new small-calibre bullets and those caused by less recent forms of projectiles. His verdict is favorable. The soft parts are less bruised, and the bones less shattered. At fighting distances the bullets hardly ever remain in the body, and the wounds are smooth, clean, and of small diameter—conditions giving fair chances of recovery.

A LETTER OF PROFESSOR VIRCHOW.—Professor Virchow has published the following circular letter under date of October 25, 1891: "The completion of my seventieth year has been a cause of rejoicing to my friends more than to myself. Age, even when it does not make its full burden felt, hints at the need of resignation. My friends, however, resolved that I should once more enjoy on my birthday, a general survey of my past life, my endeavors, my labors, my successes. And they have had their way. From almost all parts of

the world the heartiest congratulations, many splendid gifts, not a few high, even the highest honors have come to me. A series of festal days elapsed and I have not even read all the letters and documents, nor estimated the measure of the recognition and attachment dedicated to me. Playmates of my early youth, schoolfellows, fellow-laborers from all directions and countries, down to my youngest pupils in the laboratory, have appeared to congratulate me. It is impossible for me to thank each individual and each body as I should like, and to tell them how happy and honored I feel that so much friendship, so much love, so much good will, still is felt for me, and how much I wish that none of it may be lost during the remainder of my life. I trust I may be permitted to express my feelings in this general letter. Only one thing I will add. My friends may rest assured that their recognition will not corrupt my heart, and that I cherish no dearer hope than that I may be permitted to consecrate my powers yet awhile, as before, to the cause of science and mankind. — **REDOLF VIRCHOW.**

**A QUESTION OF SATISFACTORY RESULT OF FRACTURED PATELLA.**—A case of interest to Surgeons came before the Supreme Court of the State of New York during a recent session in Plattsburgh. In May, 1888, a man, by a kick of a horse, supposed rupture of his left ligamentum patellæ. A surgeon attended him for two months or more, during a portion of which time the patient did some of his farm work. The union proved to be ligamentous, and was perhaps two and one-half inches long. The patient brought suit to recover \$10,000, for malpractice. At the close of the prosecution, counsel for defence moved a nonsuit on the ground that the evidence had failed to show that the present condition of patient's patella was in any manner due to neglect or non-skillful treatment on the part of defendant. After some argument, the Court decided to hear the defence and then give an opportunity for renewal of the motion. Much valuable expert evidence was given, to the effect that the result was a fair average, and that the defendant had properly treated plaintiff's fracture. As the evidence of both plaintiff and his expert was substantially the same as that of the defendant and his experts, the Court directed the jury to bring in a verdict of no cause of action.

BOSTON.

**OPPOSED TO VACCINATION.**—An intermediate passenger on the *Catalonia*, which arrived in Boston last week, having refused to allow himself to be vaccinated, has been detained at quarantine for two weeks.

**BOSTON STREETS.**—At the last meeting of the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, the improved condition of the streets of Boston was commented upon. A full report of the meeting will be published in an early issue of the *JOURNAL*.

**REQUESTS TO PUBLIC INSTITUTIONS.**—By the will of the late Mr. T. O. H. P. Burnham the follow-

ing institutions among others are given legacies: Boston Dispensary, \$2,000; Children's Hospital in Boston, \$5,000; Children's Home on Tyler Street, \$5,000; Boston Lying-in Hospital, \$5,000; Consumptives' Home in Boston, \$2,000; New England Hospital for Women and Children in Boston, \$2,000; Perkins Institution and Massachusetts Asylum for the Blind, \$5,000; Massachusetts Society for Aiding Discharged Convicts, \$2,000; Massachusetts School for Idiotic and Feeble-Minded Children, \$5,000; Asylum and Farm School for Indigent Boys, \$5,000; Washingtonian Home in Boston, \$5,000; Massachusetts Institute of Technology, \$20,000; Tufts College, \$10,000; Massachusetts Agricultural College at Amherst, \$5,000. The Massachusetts General Hospital is the residuary legatee, and as the estate is large, it is hoped that the hospital may ultimately receive a large bequest.

NEW YORK.

**ACADEMY OF MEDICINE.**—On Thursday evening, November 19th, at the Academy of Medicine, the Anniversary Discourse was delivered before the Fellows of the Academy and a large number of invited guests by Prof. Charles I. Chandler, who took for his subject, "Arsenic in Common Life." Afterwards a collation was served.

At a meeting of the Section on Public Health of the Academy of Medicine, held November 18th, Dr. Stephen Smith read a paper on "The Office of Coroner, with Suggestions of Reform in the City of New York." In it he advocated the abolition of the coroner's office; believing that the work now entrusted to the coroners could be more efficiently done by the Health Department and the District Attorney's office. In the discussion on the paper, Dr. Doulin, who at present holds the position of Deputy Coroner, spoke in favor of retaining the office of coroner, but made the following suggestions for improving the efficiency of the latter: increase the number of coroner's physicians; provide the morgue with more suitable appliances for making autopsies and for pathological research; provide the coroner's office with scientific apparatus and secure from it the publication of reports which would command the attention of the medical world.

**DEATH OF A FASTER.**—George Stratton, a man who attempted to fast for forty-five days, at one of the dime museums, has died from the results of fasting. After going for thirty-seven days and one hour on water alone, his physicians ordered him two teaspoonfuls of champagne a day. At the end of forty-one days and eighteen and one-half hours, however, symptoms of heart failure became so marked that it became necessary to stop the fast at once. The champagne which was given him while in the extremely debilitated condition that he was, appeared to bring on alcoholism, and the next day he was transferred to Bellevue Hospital. Here he was treated with stimulants and peptonized food, but was unable to rally, and died two days after admission, November 19th. The au-

topsy showed death resulted from cerebral congestion caused by alcohol, with fatty degeneration of the heart as a contributory cause. Stratton was a man thirty years old, and of immense physique. At the commencement of his fast he weighed 270½ pounds, and at the end of it 211 pounds, 8½ ounces, a loss of nearly 60 pounds. Five other contestants commenced the fast with him on October 5th, but these all dropped out after abstaining from food for various periods varying from six to twenty days.

**VERDICT AGAINST A DRUGGIST.**—In a suit for \$10,000 damages brought against a Brooklyn druggist in consequence of the substitution of corrosive sublimate for chloral hydrate in a prescription compounded by a clerk in his shop, the jury has awarded the plaintiff \$4,000 damages. The clerk actually put up four drachms of bichloride of mercury (twenty grains to the dose), in place of the chloral ordered by the prescription. Fortunately, the patient vomited nearly all of the dose he took, but he made a narrow escape with his life, and still continues to suffer from the effects of the poison.

**THE UNION FOR CONCERTED MORAL EFFORT.**—The first of a series of public meetings under the auspices of "The Union for Concerted Moral Effort," which is designed to enlist the sympathy and good offices of citizens of all shades of religious belief, was held on November 19th. It is stated that the first object of the movement is to secure more parks and playgrounds for the children in the crowded tenement-house districts.

**THE WOMAN'S HOSPITAL.**—The thirty-sixth anniversary of the Woman's Hospital was celebrated at the hospital buildings on November 19th. The report of the work for the year, which was presented by Dr. Clement Cleveland, showed that 689 in-door and 1,481 out-door patients had been treated.

## Miscellaneu.

### FASHIONS IN DOOR-PLATES.

The custom in different cities as to door-plates and signs of physicians is described in the *Post-Graduate*.

In London a large door-plate of brass or silver is the thing. In the West End of that city, doctors seem to live together, and one may see two or three in the old-fashioned, very neat English-basement houses, that are to be found in such great number in Harley Street, Brooke Street, George Street, Grosvenor Square, and so on. In Brussels, the outside of the house is sometimes decorated *à la* New York, but generally with more taste. There, professional men do not hesitate to announce their specialty. In Berlin, where a celebrated man may be one or more flights up, a porcelain plate neatly inscribed with black letters, sometimes with the specialty, and always with the office hours, is in good form.

In Paris, there is such an absence of signs or door-plates that it is in many instances difficult to know that you are at the right house, so modest or negative are

the indications. In Paris, too, distinguished specialists, sometimes live very high up, in great apartment houses without elevators. But some of the great Paris physicians live magnificently in town, and have fine country places as well.

Philadelphia and Boston, outdo New York, in the magnitude and splendor of door-plates and office-signs. It is doubtful if they are ever of any particular use, except for those who are looking for a doctor in an emergency.

### A METHOD OF REMOVING AN ACUTE PNEUMOTHORAX.

The pneumothorax is a dangerous complication of penetrating wounds of the chest, partly interfering with respiration, partly with the circulation by pressure on the heart and large vessels. Dr. Witzel<sup>1</sup> recommends a method, which was tried in a case in Trendelenburg's clinic. His idea is to change the pneumothorax into an artificial hydrothorax and then to empty this by aspiration.

The bleeding having been arrested, a male catheter of metal is introduced into the pleural cavity through the highest points of the wound, its beak being parallel with the chest wall. The wound is thereafter closed by sutures, both air- and water-tight, with the exception of a little opening at the highest point. The pleural cavity is now generally filled with a solution of boracic acid, of the temperature of the blood, till all the air is expelled through the catheter, and all the fluid is then removed by depressing the irrigator, which then acts as a syphon. The case treated in this way progressed very favorably. The respiration was quiet and regular after the operation, the percussion and auscultation normal.

### STERILIZATION OF MEDICINES FOR HYPODERMIC USE.

On making gelatine plate cultures from the more commonly-used hypodermic solutions, Dr. Marinucci reports in *Riforma Medica*, October 25th, that some, especially those of eserine and morphine, were teeming with bacteria.<sup>2</sup> He next proceeded to test the effects of sterilization on the above solutions, the method employed being either to boil them or to expose them for a time to a temperature of 100° C. in a Koch's steam sterilizer. He then tested the activity of the solutions thus treated as compared with the same before sterilization, and came to the following conclusions: In all the preparations studied there may develop microbes, of which, however, probably not all are harmful. Sterilization by heat does not alter solutions of strychnine, curare, bi-hydrochlorate of quinine, or borate of eserine; encephalins, but does not alter the character of the action of morphine and atropine, so that the sterilized liquids must be used in larger doses than the non-sterilized ones; it seriously alters sulphate of eserine, rendering the solutions in great measure inert. The solutions unaffected by heat may be sterilized simply by boiling for a time in a *bain-marie*. It is recommended also to sterilize the hypodermic syringes in the same manner. For those solutions which are found to be altered by heat, an

<sup>1</sup> Annals of Surgery, November.

<sup>2</sup> British Medical Journal.

excellent method of keeping them sterile is to add corrosive sublimate in the proportion of 1 to 10,000. This is perfectly efficient, and is in no way harmful to the active drug.

### TRANSFORMATION OF THE SMALL-POX VIRUS.

At the Académie de Médecine M. Chaveau read a long paper on the relations existing between small-pox and vaccine as regards the transformation of the virus.<sup>1</sup> He said that the idea that vaccine was only a transformation of small-pox continued to obtain a large number of partisans. He, on the contrary, believed that the virus in both cases proceeded from the same origin. It was true the absolute proof was not yet established, but that they were distinct affections he did not doubt. Attempts were made by a Lyons committee to transform human small-pox into vaccine by inoculating cows, but the virus remained the same as to its nature even after several cultivations, consequently it must be accepted that the simple passage of pox virus in the organism of the cow or horse is entirely incapable of changing this virus into vaccine. Vaccine never produced small-pox in man, nor did human small-pox ever become vaccine when inoculated into animals. Vaccine is not, consequently, an attenuated small-pox.

### A CHINESE PATENT MEDICINE.

CHINA is said to be fully as far along as the United States in the number of secret medicines advertised for sale. The following advertisement, from a Chinese newspaper, has recently appeared in the *Cornhill Magazine*, and goes to show that the American proprietary medicine advertiser has still something to learn from his oriental representative:

"This receipt has come down to us from a physician of the Ming Dynasty. A certain official was journeying in the hill country when he saw a woman passing southward over the mountains as if flying. In her hand she held a stick, and she was pursuing an old fellow of a hundred years. The mandarin asked the woman, saying, 'Why do you beat that old man?' 'He is my grandson,' she answered; 'for I am 500 years old, and he 111; he will not purify himself or take his medicine, and so I am beating him.' The mandarin alighted from his horse, and knelt down and did obeisance to her, saying, 'Give me, I pray you, this drug, that I may hand it down to posterity for the salvation of mankind.' Hence it got its name, the 'Faïr Recipe for Lengthening Life.'

"It will cure all affections of the five intestines and derangement of the seven emotions, constitutional debility, feebleness of limb, dimness of vision, rheumatic pains in the loins and knees, and cramp in the feet. A dose is one-quarter ounce. Take it for five days, and the body will feel light; take it for ten days, and your spirits will become brisk; for twenty days, and the voice will be strong and clear, and the hands and feet supple; for one year, and white hairs become black again, and you move as though flying. Take it constantly, and all troubles will vanish, and you will pass a long life without growing old. Price per bottle, 3s. 3d."

### THERAPEUTIC NOTES.

EXPECTORANT. — Rossbach<sup>1</sup> recommends the following:

R Morphine hydrochlor. . . gr. ½.  
Apomorphine hydrochlor. . . gr. ½ to gr. i.  
Acidi hydrochlorici dil. . . gtt. x.  
Aque . . . 3 ss. M.  
Sig. Descriptioful every two hours.

A NEW BORON PREPARATION. — Jaenicke<sup>2</sup> states that a substance, which is readily made by heating equal parts of boric acid, borax and water to the boiling-point, has proved of great service to him as an antiseptic in a number of cases, especially in the treatment of suppurative affections of the ear, employing sixteen per cent. solution of the crystals which deposit from the above mixture when allowed to cool.

AMMONIUM CHLORIDE IN EPIDEMIC INFLUENZA.<sup>3</sup> — In a paper recently read before the Academy of Medicine in Paris, M. Marrotte advocates the use of ammonium chloride in the treatment of epidemic influenza, more especially in those forms of the disease which are complicated with pulmonary congestion or inflammation. From 48 to 80 grains (three to five grammes) are given in twenty-four hours in the form of eight-grain powders, which may be conveniently concealed in wafers.

### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 14, 1891, TO NOVEMBER 20, 1891.

CAPT. EDWIN F. GARDNER, assistant surgeon, U. S. A., is relieved from further duty as attending surgeon and examiner of recruits in New York City.

Leave of absence for one month is granted CAPT. CHARLES RICHARD, assistant surgeon, U. S. A.

Leave of absence for one month, to take effect about the 15th inst., is granted BENJAMIN L. TEN EYCK, assistant surgeon.

FIRST LIEUT. HENRY C. FISHER, assistant surgeon (recently appointed), ordered to Fort Riley, Kan., for duty.

FIRST LIEUT. HENRY A. SHAW, assistant surgeon (recently appointed), ordered to Fort McKinney, Wyo., for duty.

FIRST LIEUT. SAMUEL R. DENNIS, assistant surgeon (recently appointed), ordered to Fort Sill, Oklahoma Territory, for duty.

FIRST LIEUT. CHARLES F. KILFEE, assistant surgeon (recently appointed), is assigned to duty at Fort Sheridan, Ill.

FIRST LIEUT. FRANK P. MEINERTHEIM, assistant surgeon (recently appointed), is assigned to duty at Fort Adams, R. I.

CAPT. EDGAR A. MILLERS, assistant surgeon, is relieved from duty at Fort Snelling, Minn., and assigned to duty at Fort MacPherson, Mich.

FIRST LIEUT. CHARLES WILLCOX, assistant surgeon, is relieved from duty at Fort Bowie, Ariz. Terr., and assigned to duty at Fort Gaiton, Cal.

### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 14, 1891.

THOMAS WOODVERLOW, medical inspector, placed on the retired list, November 13, 1891.

P. H. BRYANT, assistant surgeon, detached from Coast-Survey Steamer "Gedney," and wait orders.

W. H. JONES, surgeon, ordered to examination preliminary to promotion.

### SOCIETY NOTICE.

**SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.**—This Section will hold its regular monthly meeting at 19 Boylston Place, Wednesday evening, December 2, 1891, at 8 o'clock.

Dr. George Haven will read a paper on "Rupture of the Uterus," and will report a case treated by abdominal section; Dr. Edward Reynolds will report two cases of ruptured uterus treated expectantly; Dr. M. H. Richardson and Dr. J. G. Mumford will report a case of cyst of the pancreas; Dr. E. W. Cushing will make a report and show specimen of uterine tumor removed by abdominal and vaginal section.

CHARLES L. SCUDDER, M.D., Secretary.

### SUFFOLK DISTRICT CENSORS' EXAMINATION.

The Censors of the Suffolk District Medical Society, officiating for the Society at large, will meet for examination of candidates for admission to the Massachusetts Medical Society, at 19 Boylston Place, on Thursday, December 17, 1891, at 2.30 P. M.

Candidates should make personal application to the Secretary, and bring their medical diploma, or its equivalent, at least three days before the examination.

For further particulars, apply from 2 to 3 P. M. to J. J. MIXOT, M.D., Sec'y, 188 Marlborough St., Boston.

### APPOINTMENTS.

HAROLD C. ERNST, M.D., has been appointed Assistant Professor of Bacteriology in the Harvard Medical School.

HENRY F. LEONARD, M.D., M.D.V., has been appointed Clinical Lecturer in the Harvard School of Veterinary Medicine.

EUGENE G. HOITT, M.D., has been reappointed Medical Examiner in Middlesex County.

CHARLES W. TOWNSEND, M.D., has been appointed Physician to Out-patients at the Massachusetts General Hospital.

### RECENT DEATH.

NATHANIEL C. HUSTED, M.D., of New York, died in Tarrytown, November 10th, aged sixty-five. He graduated from the Medical Department of the University of the City of New York in 1850. During the war he served with distinction as surgeon. He has been for some time well-known among the medical men of the country. He was a frequent contributor to medical literature, and has held many positions of honor and trust.

### BOOKS AND PAMPHLETS RECEIVED.

Local Boards of Health in the State of New York. Issued by the State Board of Health. Albany. 1891.

The Climate of Southern California in Relation to Disease. By William A. Edwards, M.D. Reprint. 1891.

Records of the Association of Acting Assistant Surgeons of the United States Army, A.D. 1891. Edited by W. Thornton Parker, M.D. Salem, Mass.: Salem Press Publishing and Printing Co. 1891.

A Practical Treatise on the Diseases of Women. By T. Galland Thomas, M.D., LL.D. Sixth edition. Enlarged and thoroughly revised by P. P. Munde, M.D. Philadelphia: Lea Brothers & Co. 1891.

Twenty-second Annual Report of the President of the Inebriates' Home, Fort Hamilton, N. Y., for the Year 1889. Twenty-third Annual Report of the President of the Inebriates' Home, Fort Hamilton, N. Y., for the Year 1890.

A Manual of Practical Obstetrics. By Edward P. Davis, A.M., M.D., Clinical Lecturer on Obstetrics in the Jefferson Medical College, etc. With one hundred and forty illustrations. Philadelphia: P. Blakiston, Son & Co. 1891.

History of Circumcision from the Earliest Times to the Present. Moral and Physical Reasons for its Performance, with a History of Eunuchism, Hermaphroditism, etc. By P. C. Remondino, M.D. Philadelphia: F. A. Davis. 1891.

## Original Articles.

SOME CASES OF DILATED STOMACH.<sup>1</sup>

BY ELBRIDGE G. CUTLER, M.D.

CASE I. M. F., thirty-five, married, housewife, born in Nova Scotia, living in Natick, had a good family history. Measles and scarlet fever in childhood. General health good till one year ago. Catamenia at seventeen, regular, painless; married at nineteen, had two children, no miscarriages. No catamenia for the past three months.

For past five years has suffered occasional dyspeptic disturbances, having distress after eating, occasional vomiting, constipation. For intervals of weeks free from symptoms. One year ago attacks became more frequent, with severe epigastric pain coming on soon after eating or independently of food, and frequent vomiting. Ten months ago vomiting of a considerable quantity of brownish material which she was told by her physician was blood. Past six months marked loss of flesh and strength (one hundred and fourteen to seventy-eight pounds), frequent attacks of pain in the epigastrium, sharp, cutting, coming on especially at night, lasting several hours, often requiring opiates for relief. Frequent vomiting of food, sometimes of dark, brownish material. Has been confined to bed for four months, and on a careful diet has been almost free from vomiting for three weeks past. No jaundice. Bowels usually constipated, at times diarrhoea. No blood observed in stools. Patient much emaciated, anæmic, cachectic. Tongue pale, clean. Pulse small, compressible. Heart: soft, systolic murmur over pulmonary area. Lungs negative. Abdomen: slight epigastric tenderness most marked at tip of sternum and over upper division of the right rectus muscle; no tumor felt in any position of patient. Right rectus muscle held firmly contracted. Urine pale, acid, 1,013, no albumen, slight sediment.

Was given four ounces of milk every two hours, and four ounces of beef juice daily. No pain, distress or vomiting from food. The stomach was washed out and distended with air when the right border was found in the right mammary line, the upper border at the level of the fifth rib, the greater curvature a hand's breadth below the umbilicus, and all the intervening space gave the same tympanic resonance (see Fig. 4).

Next day gave a test-breakfast of meat, tea, toast, at six A. M.; washing at ten A. M., using cubic centimetres warm water; about three pints of thin, watery material obtained, containing fragments of undigested food and some mucus. Slight butyric odor. Hydrochloric acid in large amount found in the washing. Iodide of potash, five grains in a gelatine capsule given when the stomach was empty, showed the reaction faintly in eleven minutes. Salol gave no reaction up to four and a half hours, and given later, not in six. Undigested food was found in the stomach repeatedly at the end of eight hours. The stomach was washed out at frequent intervals, and hydrochloric acid was always found. She began to pick up in flesh and strength immediately, and lost her pain and vomiting. Very soon the residual, if I may use the term, was reduced to two instead of three pints. Full inflation after emptying the stomach showed that it

nearly filled the abdomen, and three quarts of water were easily introduced without any discomfort. The patient having improved so much as to be quite comfortable, passed out of observation.

CASE II. T. J. T., referred to me by Dr. M. H. Richardson, July 22, 1890, a plumber by trade, aged forty-six, married, born and living in Boston. Had suffered from dyspepsia for some time, together with constipation; of late there had been an exacerbation of the trouble. Vomiting had been a symptom of some duration. The vomitus was frothy and smelt like yeast. There had been constipation, pain in the upper right portion of the epigastrium after food, and a sour stomach for the past four months. Vomiting occurred daily after meals a little, and every three or four days was in large quantity. When first seen he was very thin, weighing one hundred and five pounds, usual weight being about one hundred and seventy. There had been much loss of strength, so that he was unable to work and could not ride on his cart. The skin was very dry and wrinkled, the urine was scanty, he had an ashy countenance, the mouth tasted bad, and he looked very ill and miserable. The stomach, when blown up, was found to fill the abdomen except in the right hypochondriac and epigastric regions, and it reached nearly to the pubes. When washed out it readily held three quarts. The tests showed the motor activity to be almost nil. The first washing brought up seeds of a preserve taken nearly three weeks before. He was regularly washed out, a diet was prescribed, Carlsbad salts, an antiseptic and nutrient enemata were used, and later, a bitter, malt and iron prescribed. He went on unintermittently well, the vomiting, pain and general discomfort disappearing very soon. The treatment has been pursued through the year and after the first few weeks he was able to resume his usual occupation without trouble. When seen recently he looked nearly as well as ever.

CASE III. H. F., plumber, aged thirty-nine, born in Cambridge, living in Brookline. Was seen October 27, 1890, and the following history obtained: Habits: moderate use of tobacco, very little alcohol, beer occasionally; family history, good; previous history, not very robust, but no serious illness. Bronchitis several years ago. Twelve years ago trouble with stomach similar in many respects to present attack, but he seldom vomited then, and distress came on immediately after eating.

Present illness began in August, with vomiting once a day, not very much at a time. Vomitus consisted of food and slimy stuff, sometimes yellow, sometimes color of milk. Much gas was passed by the mouth and also by the rectum, from the bowels. Seldom any sour fluid in the mouth. Very constipated, but bowels moved by drugs in small doses. Distress in stomach now is two or three hours after eating, and is frequently relieved by food. Has no feeling of distension or weight, but more an "empty feeling." Thinks he never had any sensitive point over stomach, or pain sharply localized, or pain in the back. Thinks he never vomited anything resembling blood or coffee grounds. Considerable loss of strength and has lost twenty pounds in weight in last two months. Has done some work right along, though the vomiting has persisted for past two months. He is a medium-sized, well-developed, rather thin man. Chest negative. Abdomen, when in the erect position, sunken in at epigastrium, and balloon-like below the umbilicus; left

<sup>1</sup> Read before the Boston Society for Medical Improvement, October 12, 1891.

hypochondriac region more prominent than right. Tympanitic on percussion over epigastric, left hypochondriac, umbilical, and both lumbar regions, flat over rest of abdomen. Stomach-tube introduced, the organ washed out, and blown up with air, gave a tympanitic area of uniform note, on percussion, as shown in figure. Urine pale, neutral reaction, 1,005 specific gravity, no albumen.

Salol given in five-grain capsules after a test-meal, and the urine tested every half-hour with liquor ferri chloride, failed to show the presence of salicylic acid up to the fifth hour. Iodide of potash given in three-grain capsules and the saliva tested with nitric acid and starch, showed the first faint blue color in seventeen minutes, not deep till twenty-two minutes. A test-meal given, the stomach-tube passed, and some of the contents expressed gave a very strong acid reaction, which was found to be due to an abundance of hydrochloric acid. The stomach was washed out daily for several days, and hydrochloric acid always found. He was taught to wash himself with the aid of his wife, and after regulation of the diet, was dismissed to report in a month, the patient saying he already felt some relief after only five washings, his appetite was better, and the bowels were beginning to act naturally. He has been seen a number of times since, and has been able to do full work, but has to be washed out every third or fourth day. Has taken malt, iron, and other tonics with benefit.

CASE IV. J. G., married, aged twenty-eight, born in New York, living in Fitchburg, a cotton-weaver, has the following history, July, 1891. His father died of a paralytic shock, three brothers and sisters died of consumption, one of brain fever, his mother, one brother and one sister are living and well. Personal habits are moderately alcoholic, excessive use of tobacco. Had gonorrhoea eleven years ago, and a sore at the same time, was followed by sore throat, sores in mouth, eruption over body, and falling of the hair.

Personal history: Never sick till four years ago. First trouble was with the stomach. For the first two years he worked part of the time, but for the past two years has not worked at all. At first had sharp pain in the epigastrium less than half an hour after eating, vomiting of food and various colored stuff followed. Relief always came from the vomiting. Stomach much distended at times. Gaseous eructations, much gas also passed with the stools. Pain in the back very severe at times. Bowels usually move without medicine, though infrequently. Four years ago weighed one hundred and thirty-nine and one-half pounds, now during past year has lost from one hundred and sixteen at the beginning of the year to one hundred and seven now. Is very nervous, but sleeps tolerably well.

Urine pale, acid, 1,007 specific gravity, albumen a very faint trace, sediment considerable, and consists of flat epithelium cells, leucocytes, mucus, and urethral gonorrhoeal strings, with a few uric acid crystals.

Examination: Rather tall, poorly developed, emaciated, marked pallor. Heart and lungs negative. Abdomen has a loose, relaxed wall, sinks in at epigastrium, protrudes below in the erect position, sense of fluctuation marked over protuberant portion with a wave on percussion, succussion on palpation. Stomach evidently much enlarged. Washed out with tube, contents very foul smelling. Abundance of free hydrochloric acid in washings. Stomach held five

quarts of water without discomfort, and when filled with air took up the entire abdomen (see figure). Motor activity proved to be much diminished. Peptonized milk six ounces every two hours, beef juice eight ounces daily, scraped beef at noon. Next day washed out again and a slice of dry toast added to diet-list daily. The washings of the next two days gave great relief from discomfort each time. Patient less nervous, sleeping better, complains less of all symptoms, no vomiting since the treatment began. Complexion less muddy. Toast had to be omitted. Salicylate of sodium five grains three times a day, and Carlsbad salts, a teaspoonful once a day in eight ounces of hot water. He went on very well for a few days, when he surreptitiously took some boiled rice, which produced disturbance, and was not all removed for two days. After ten days of treatment he had become so much better that he was allowed to go home, feeling much stronger, with a better color and complexion, and feeling much elated. He was advised to continue the lavage once a day, and to use bicarbonate of soda with it, to take salicylate of sodium two grains three times a day, the diet was carefully prescribed, and he was to continue the Carlsbad and report in a month.

September 11th he was found to be immensely improved in every way, and thinking he could work a little, he was allowed to do so.

October 9th he had increased in flesh and strength markedly, and had been able to work for three weeks without much trouble.

CASE V. S. G. J., aged forty-two, farmer, born and living in Raynham, single, weighs one hundred and twenty and a half pounds, July 2, 1891. Family history negative. Personal history, always well. Present illness began February 7, 1889, when he was taken with what his physician called "dumb ague," that is, he had slight fever, chilly sensations but no marked chill, vomited everything. This continued for three months. Since then has had attacks of nausea and vomiting at irregular intervals. Vomitus contains considerable mucus, but no blood. Took an ocean trip of three weeks in June, 1891, and was much relieved thereby. Complaints of considerable gas on the stomach and palpitation of the heart. Has lived on milk and Mellin's food chiefly of late. Bowels constipated. Has lost twenty-five pounds in two years. He is short, well-built and fairly nourished. Tongue coated, face pale, but not otherwise remarkable. Lungs and heart negative. Abdomen a little distended below umbilicus. Urine normally acid, 1,011, no albumen. Given milk with broths, and beef juice, three ounces, twice daily. Salicylate of sodium, five grains, thrice daily and sulphate of magnesium in the morning. Two days later vomited soup. Had chilly sensations all day. Quinine, two grains, three times a day. Next day much better, sat up and went out doors. A few days later occasional vomiting after a meal, and complained of considerable gas in the stomach. Diet increased by two raw beef sandwiches daily, and the sulphate of magnesium was increased. Next day suide bread was added to diet. Two days later complained of many curious sensations in various parts of the body, especially in the stomach and pharynx. He then had a test-breakfast given, and was washed out with the stomach-tube. Washing showed abundant hydrochloric acid. The capacity of the stomach was found to be moderately increased over the normal, holding two quarts readily. The motor activity was

found to be diminished. The patient perceived that the washing was beneficial, and asked to have it more frequently. He soon said he did "not know that he had a stomach" in the afternoon; in the morning, however, has eructations of gas, and occasionally a little fluid, some distension and nausea. He was then taught how to use the tube himself, and was advised to wash out twice a week, to take Karlsbad salts daily or every second day, to take quinine thrice a day one grain, and was sent home to report in a month.

September 29th. Weight one hundred and thirty-five pounds. No vomiting since discharge, no pain, no eructations. Bowels have moved daily with the salts taken every second day. The treatment was continued, the patient being jubilant over his condition.

FIG. 1. Position of normal stomach when distended with air. *c*, Cardiac end. *p*, Pyloric end. *g.c.*, Greater curvature. *l*, Liver, lower border.

CASE VI. A. M. W., seen in consultation with Dr. E. S. Boland, of South Boston, June 12, 1891. His history had been one of gastric distension, pain, uneasiness, discomfort, gaseous eructations, vomiting, loss of flesh and strength, inability to pursue his usual occupation of a business man. His appearance was quite characteristic, the countenance was sallow, he was very emaciated, weighing but one hundred and nineteen pounds, the epigastric sinking in and bulging out lower down in the abdomen was marked. The usual methods of examination were pursued, and the stomach was found to be markedly dilated, filling the greater part of abdomen. Regular washing was done by Dr. Boland, the diet and regimen was carefully marked out, certain necessary medicaments were given, and the patient began to improve at once. All his troubles were very much lessened, and on July 8th the weight was one hundred and twenty-five and one-half pounds. Hardly any gas or wind complained of.

July 24th, he had increased to one hundred and thirty and one-half pounds and had hardly any symptoms.

August 3d, had gained two pounds more.

September 14th, the weight was one hundred and thirty-six pounds. Had vomited three times since last visit, due to some errors of diet. Had gone in to his business, and borne it well. Liberal additions to his diet were made, and he was to report again in six weeks,—treatment meantime being continued.

A cursory glance even, at the Figures 1, 2, 3, which

I pass round, drawn from subjects by Rosenheim, will show that the position of the greater curvature taken alone, as is usually done, gives no full information as to the true size of the stomach. It is perfectly evident from them that the mere passage of a sound to any given point, as to a hand's breadth below the umbilicus, will not necessarily indicate an enlarged stomach. For in both the vertical stomach, and in the one with downward displacement of the whole organ, this greater curvature reaches several finger breadths below the umbilicus. We can only consider the organ to be enlarged when the tympanitic resonance begins at the fifth rib in the anterior axillary line, and the right border of it reaches the right mammary line, and the lower border extends below the

FIG. 2. The vertical position of the stomach of normal size, blown up. *c*, Cardiac end. *p*, pyloric end. *g.c.*, Greater curvature. *l*, Lower border of liver.

FIG. 3. Displacement downward of the normal stomach, blown up. *c*, Cardiac end. *p*, Pyloric end. *g.c.*, Greater curvature. *l*, Lower border of liver.

umbilicus, and all the intervening space has the same tympanitic note on percussion. Such a stomach will readily hold more than a quart and a half of fluid or more than seventeen hundred cubic centimetres. Furthermore, there must be an interference with the motor function of the stomach if the organ be dilated and secondarily delayed absorption.

The symptoms which would lead one to consider the

possibility of dilated stomach are disturbed nutrition, constipation, dyspepsia, pressure, sense of fulness, foul eructations, pain, and lastly, vomiting. Examination of the abdomen shows a relaxed wall with sinking in of the epigastrium and distension at or below the umbilicus. The skin is dry, wrinkled, and furfuraceous, the subcutaneous fat is diminished, there may or may not be tenderness in the epigastrium, the face is ash-colored, the appetite is apt to be perverted, thirst is slight, constipation is the rule, rarely occasional diarrhoea, the tongue is frequently coated. The general discomfort is apt to be increased by taking food, so that pressure, sense of fulness, distension of the body, perhaps headache, bad taste in the mouth, acid, foul eructations and pain usually follow, which latter may be colicky, and increase till vomiting relieves it somewhat. The vomiting is apt to be frothy, yeasty in odor, occurs after each meal, and every few days is frequently very large in quantity, consisting of more or less altered food. If no contraindication exists, examination with the stomach-tube will usually enable one to establish the diagnosis.

FIG. 4. Position of dilated stomach when blown up. *c*, Cardiac end. *p*, Pyloric end. *g*, *g*, Greater curvature. *l*, Lower border of liver.

The treatment is dietetic and mechanical. The following points in reference to the diet are to be observed:

(1) The taking of fluid is to be reduced as far as possible, as absorption from the stomach is impaired. Fluid forms the chief part of the stagnating contents, and helps increase the dilatation by its bulk and weight. Large quantities of liquid retained, help dilute the hydrochloric acid which is secreted, and thereby in many cases render peptonization difficult and facilitate the occurrence of decomposition and fermentation. How much fluid is permissible depends on the habits and characteristics of the patient. In general we may consider that about one quart *per diem* should be the maximum taken by the mouth.

(2) Solid food in small quantities should be taken about six times a day. Regard should be paid in the selection of this food to the general condition of nutrition and to the cause which underlies the dilatation.

(3) As a rule the food and drink should be cold.

(4) The kind of food should depend on the gastric secretion. If this be normal or over-abundant, a moderate quantity of carbohydrates, rather more abundant

fat, and a generous supply of albuminous substances is to be allowed. If there is diminished production of hydrochloric acid and fermentation exists, we must diminish and carefully select the carbohydrates and fat, and give a moderate quantity of albuminous food with glutenous substances and wine. In enfeebled conditions a little tea and coffee may be added. Certain of the coarser articles of food must be denied, as brown bread, potatoes, cabbage, green vegetables, pickles, salads, peas, beans, etc. Frequently nutrient enemata are advisable at regular times twice a day, or rectal injections of water to supply the fluid needed by the body.

The mechanical treatment, namely, washing out the stomach, is the most important proceeding, as it removes in great part the troubles about which the patient complains. It stops the vomiting, discomfort, and all the dyspeptic symptoms, the headache and the feeling of weakness. It rouses the appetite and restores the movements of the bowels. At first it should be done once a day only, later as the condition becomes better, every second or third day may suffice. It is immaterial so far as the diseased condition of the stomach is concerned, what part of the day be selected for the washing out, whether morning or night, provided it be six or seven hours after a meal. It is only to be borne in mind that when done at night the patient is more apt to sleep better for it. The lavage should be made with lukewarm water till the stomach is thoroughly cleansed, when different solutions may be added to advantage. With much fermentation, antiseptics claim the first attention. When there is little or no fermentation, alkalies are substituted. Massage and electricity are frequently added to help restore the lost motor activity in suitable cases. Medicaments to control or counteract different symptoms are constantly demanded. Relatively few cases are benefited by surgical interference.

## THE DISTRIBUTION OF DIPHTHERIA IN MASSACHUSETTS.<sup>1</sup>

BY SAMUEL W. ARDOTT, M.D.,  
Secretary to the State Board of Health.

(Concluded from No. 22, page 561.)

The other class, embracing the cities and manufacturing towns, 92 in number, had a population of 1,342,421 in 1880, an average of 14,591 to each city or town. These towns are much more densely populated than the former class. Most of them have a steadily increasing population, a large portion of which consists of immigrants, either of European nativity or from the British North American provinces. Five only of the towns of this class had less than 3,000 inhabitants. In many of the towns of this class there is a rural population of considerable size living in those portions outside the more densely settled villages. The actual increase in population in the rural towns, for the period of twenty years, between the census of 1870 and that of 1890, a period nearly coincident with that under consideration, was 11½ per cent., while that of the larger or manufacturing and urban districts was 70 per cent. Certain exceptional cities and towns

<sup>1</sup> Read at the Seventh Meeting of the International Congress of Hygiene and Demography, London, August, 1891.

In this paper it is to be understood that the data given includes *fatal* or *non-fatal*, since it is generally conceded by the physicians of Massachusetts that fatal cases, so far as the registration returns are concerned, cannot well be separated from diphtheria.

in this group are worthy of notice. Newton is neither a manufacturing nor a densely settled municipality, but a suburban residential city, with a population consisting mainly of wealthy or comparatively well-to-do inhabitants. Its general death-rate, as well as that from croup and diphtheria, has usually been low. I have placed Provincetown and Nantucket in the same group, each of which has a considerable area of nearly unoccupied sandy territory lying outside the densely settled seaport. The former had an average general death-rate, and a low diphtheria death-rate, while the latter had a very high death-rate from all causes as well as from diphtheria. Both towns are exposed to sea-breezes throughout the year.

The average annual death-rate from diphtheria and croup in the 92 densely settled towns and cities was 11.39 per 10,000 of the population, while that of the 234 rural or sparsely settled towns was 6.53 per 10,000 for the same period.

The relation of certain railway lines to the diphtheria death-rate is worthy of note. There were, during the period in question, about 2,000 miles of railway in operation in the State. Many of the towns of small size are at a considerable distance from these railways or are of so little importance that very few stations are located in such towns.

The Boston and Albany Railroad, the principal line from the seaport of Boston through the State to the West (a distance of 150 miles), carries a very large number of passengers each year, and has one or more stations in nearly every town through which it passes. The greater number of cities and towns through which this railway passes had comparatively high diphtheria death-rates. Those upon the line of the Fitchburg Railroad, another line of similar length, but having much less traffic, had lower diphtheria death-rates, while those upon the Massachusetts Central, a line of about 100 miles in length, also running east and west, but of comparatively recent construction, had, in general, still lower death-rates from the same cause.

It is also worthy of note that, out of the 28 cities, 20, including all of the most populous, except Fall River, had a death-rate from diphtheria and croup higher than the average of the State, and of these 20 were in the second group (these having from 0 to 50 per cent. higher rates than the average of the State). The remaining city, Holyoke, which had a diphtheria death-rate of 15.38 per 10,000 per year for the (1850, 3,245) period, is a thriving city of rapid growth (pop. 1890, 35,528), the principal industry of which is the manufacture of paper. It has a population in which the Canadian French form a very considerable fraction.

The metropolitan district, comprised in the city of Boston and the contiguous cities and towns of Cambridge, Somerville, Malden, Chelsea, Everett, Quincy, Lynn and Brookline, constituting a comparatively densely populated and rapidly increasing district, had a mortality-rate from diphtheria and croup which was quite uniform, and considerably above the average of the State, being very nearly 12.5 per 10,000 annually, the exception being Brookline, with a mortality-rate from these causes of 8.9 per 10,000. That of Newton, a little further out, was 7.2; and that of Woburn, 10 miles, was 6.1. Brookline and Newton are not densely populated, and the social character of their population is much better than the average of the metropolitan district.

In this connection, the effect of age distribution in

the different districts of the State should be considered, since the greatest mortality from diphtheria and croup is at the younger ages of 0 to 5 and from 5 to 10 years.

The following table shows the average annual mortality at each age-period expressed as a ratio per 10,000 of the population living at those ages, for the period of 27 years, ending with 1889:

TABLE VI.  
DEATH-RATES FROM DIPHTHERIA AND CROUP AT DIFFERENT AGES.

Ages.	Diphtheria.	Croup.
Under 5 years . . . . .	36.87	27.86
5 to 10 " . . . . .	19.89	4.63
10 to 15 " . . . . .	5.38	.29
15 to 20 " . . . . .	1.66	.05
20 to 30 " . . . . .	.80	.02
30 to 40 " . . . . .	.53	.03
40 to 50 " . . . . .	.36	.02
50 to 60 " . . . . .	.31	.02
60 to 70 " . . . . .	.54	.01
70 to 80 " . . . . .	.53	.02
Over 80 " . . . . .	.41	.06

The number of deaths from which the above table is computed are 29,422 of diphtheria and 14,590 of croup.

The range of age-distribution in the different districts is very considerable, the ratio of children under five in the smallest district under consideration, and also that which has the lowest ratio, being 6.1 per cent. in Nantucket, and the highest ratio being 10.2 per cent. in Suffolk County.

The relation of the mortality from diphtheria and croup, to the population living under five years of age, may be seen in the third column of figures in Table VII, by which it appears that the rank of some of the districts is slightly changed as compared with their position in the preceding column, in those counties that have a nearly identical rank in the second column.

TABLE VII.  
COUNTIES OF MASSACHUSETTS ARRANGED ACCORDING TO THEIR DEATH-RATES FROM DIPHTHERIA AND CROUP 1871-88, THE STATE BEING TAKEN AN 100, WITH DENSITY OF POPULATION EXPRESSED IN ACRES TO EACH PERSON.

Counties.	Density of Population, Acres to One Person.	Death-rates from Diphtheria and Croup. The State = 100.	
		Total Population.	To Children under Five.
Dukes . . . . .	18.2	13	20
Barnstable . . . . .	8.2	57	68
Franklin . . . . .	11.3	61	64
Hamphshire . . . . .	7.1	72	78
Plymouth . . . . .	4.6	75	85
Worcester . . . . .	3.5	82	78
Norfolk . . . . .	2.6	83	85
Bristol . . . . .	1.8	92	90
Middlesex . . . . .	1.2	99	97
The State . . . . .	2.3	100	100
Essex . . . . .	1.1	103	109
Hamden . . . . .	3.0	111	107
Berkshire . . . . .	7.6	115	107
Suffolk . . . . .	0.08	124	123
Nantucket . . . . .	12.7	161	251

For the sake of comparison with the excellent tables of Dr. Longstaff, presented in the Report of the Local Government Board of England of 1887, I have introduced another table intended to conform to Dr. Longstaff's classification. I have, in this table, divided the fourteen counties into three groups, to which the terms dense, medium, and sparse districts are applied, the first applying to those in which there is less than one acre to each person living. This includes only the metropolitan district of Suffolk County. The second (medium) applies to those in which there is one acre, but less than two acres, to each person. This comprises the counties of Essex, Middlesex and Bristol. The sparse districts, those in which there are more than two acres to each person, comprise the remaining counties. In this grouping, the small island counties of Dukes and Nantucket are reckoned with Barnstable County, their general characteristics, both of population and of climate, being quite similar.

TABLE VIII.

Counties arranged according to Density.	Counties.	Density, Acres to One Person.	Death-rate, Diphtheria and Croup.
Districts in which there is less than one acre to each person living.	Suffolk . . .	0.06	124
Districts in which there is more than one acre to each person but less than two acres . . .	Essex . . . . .	1.1	103
	Middlesex . . . .	1.2 av. 1.4	99 av. 100
	Bristol . . . . .	1.8	92
	Norfolk . . . . .	2.6	83
	Hampden . . . . .	3.0	111
	Worcester . . . .	3.5	82
	Plymouth . . . .	4.6	75
Districts in which there are more than two acres to each person . .	Hampshire . . .	7.1 av. 4.8	72 av. 87
	Berkshire . . . .	7.6	115
	Barnstable, Dukes, and Nantucket . .	10.1	62
	Franklin . . . . .	11.3	61

In the densely settled district, having but  $\frac{1}{10}$  of an acre to each person, the average annual mortality-rate from diphtheria and croup was 12.7 per 10,000 of the population.

In the medium districts, in which the average density was 1.4 acres to each person, the mortality-rate was 10.2 per 10,000.

In the sparsely settled districts, in which the average density was 4.8 acres to each person, the mortality-rate was 8.8 per 10,000 annually.

Assuming the mortality of the dense districts as 1,000, we have the following results:

Mortality from diphtheria in dense districts . . . .	1,000
Mortality from diphtheria in medium districts . . .	893
Mortality from diphtheria in sparse districts . . . .	609

While these figures present a result which differs from the statistics of England and Wales, it should be remembered that they are compiled from a population less than one-tenth as large, and are, therefore, less trustworthy as sources from which conclusions are to be drawn.

In another point, however, the conclusions agree with those of Dr. Longstaff, and that is, that in the

second half of the period the towns suffered, relatively, more than in the first half.

In 18 out of the 28 cities, their mortality-rate from diphtheria and croup had materially increased from the first to the second half of the period of eighteen years under consideration, and these 18 included the six largest cities in the State.

The districts which suffered most severely, taking the whole period of eighteen years, were the northern half of Berkshire County, that portion of the valley of the Connecticut River within the State, which lies in Hampshire and Hampden Counties, and the valleys of the Westfield and Chicopee Rivers, with the tributary valleys of the latter, the southern half of Worcester County, the metropolitan district about Boston, the Merrimac River valley, the southern sea-coast region of Essex County, the eastern part of Norfolk County, the eastern border of Bristol County, the north-west corner of Plymouth County, and the town of Nantucket.

Those regions which had the greatest immunity were the southern half of Berkshire County, the whole of Franklin County, the east and west parts of Hampshire County, the west part of Hampden County, the northern half of Worcester County, the north and west part of Middlesex, the north-east sea-coast district of Essex, the west half of Norfolk, the western border of Bristol, nearly all of Plymouth, and the whole of Barnstable and Dukes Counties.

In comparing the distribution of fatal diphtheria and croup in the State with that of other diseases, certain other similar inquiries relating to the other principal infectious diseases tend to show that diphtheria is "not regulated by the same causes as influence the general mortality," except that, so far as the density of population is concerned, the results of observations in Massachusetts lead us to an opposite conclusion from that which is derived from the statistics of England and Wales.

In the course of personal inspections made in many parts of the State, in city, town and country districts, my observations tend to support the following statement found in the report already quoted, with reference to the increasing severity of prevalence in towns as compared with country districts.

"If we grant for a moment the exciting cause of the disease to have its origin in the country, it is just possible that the constantly increasing communication between town and country, by affording additional opportunities of importing the disease, might account for its increased prevalence in towns.

"Although the greater proximity of people in towns would, at first sight, seem to increase greatly the chances of infection, it is by no means certain that the individuals of a town community come so much into personal contact as the dwellers in a lonely hamlet. There may be but few opportunities for the introduction of the poison into an isolated village, but once introduced there are great facilities for its spread. In a village every one knows his neighbors, whereas in a large town, dwellers in the same street are often complete strangers to each other."

In the same line of investigation, and in harmony with the foregoing quotation, the following extract from a paper presented at the eighteenth annual meeting of the American Public Health Association, held at Charleston, S. C., is herewith quoted:

"The following inquiry was directed to be made by

the State Board of Health of Massachusetts, in 1889. In a city in which diphtheria was epidemic, 100 houses were selected for examination and inspection. A recent, and quite severe, epidemic had prevailed, in which there had been 174 deaths from diphtheria in the course of the year (1889). Fifty houses were selected in which cases of diphtheria were known to have occurred within twelve months prior to the time of inspection; 50 other houses were selected in which it was known that no cases of diphtheria had occurred during the previous five years. In general terms the houses of the latter class were as nearly identical with the former in their location, construction, and the social condition of their inmates as possible. On inspection, the actual sanitary condition of these houses was found to differ but little in the two classes. Defects of plumbing, want of proper traps, leaks in drain pipes, and other similar defects, were found about equally in the two. Not one of the 100 houses had special provision for ventilation. In one point only did there appear to be a marked difference in the two classes, and that was in the ratio of damp cellars. In the houses in which diphtheria had existed, the ratio of damp cellars was as eight to five when compared to the houses of the other class. I believe this is in accord with the observations of others to the effect that where diphtheria has once been introduced from without, it finds in dampness a congenial soil for its propagation.

"If it is desired to trace the course of an epidemic of diphtheria amid the mazes of a densely crowded city, there can be no more difficult task imagined. The daily influx and efflux of population to and from the suburbs, the thronging of people in shops, markets, factories, steam-cars, horse-cars, and electric cars, the crowding together at lectures, church services, entertainments, theatres, and, finally, in the public and private schools, give the best facilities for the spread of epidemic disease. On the other hand, isolated communities occasionally present excellent opportunities for the careful study of the methods of spread of such an epidemic disease as diphtheria. Such a case presented itself to my notice during the past year. A quiet, old town in Berkshire County, near the source of the Farmington River, has comparatively little connection with the outside world. It is eighteen miles from the nearest railroad, has no hotel, and has but little regular traffic with neighboring towns. In the spring of 1888, a school-teacher, a native of this town, was employed as teacher of a school twenty-five miles distant. At the close of her term in teaching, in June, 1888, she went home ill, her illness proving, on her arrival home, to be diphtheria. Within the next six months, cases occurred in the immediate family of this young woman and those of her relatives, no quarantine having been enforced. It spread across the street to the house of the family physician. Several deaths occurred in these two families. The family of the physician was shattered, and he left the town, his house being abandoned and vacant for several months. The postmaster of the village was also the village grocer. People went to and from the post-office from the first infected house, and the grocer also made frequent visits to the house with his groceries. His family was next attacked, and so severely as to be broken up. After the house of the village physician had remained vacant several months, and some inefficient attempts at disinfection had been practised, a new

physician moved into and occupied the vacant house. Soon after moving in his children were attacked. A lying-in woman whom he attended, together with her seven-year-old boy, were both attacked. A neighbor who called upon this woman was next attacked; and so the history of this epidemic could be traced from house to house, and from one individual to another, for a period of eighteen months or more. The houses of these people, which were visited, did not appear to be especially filthy, but in two or three instances excessive dampness of the neighboring soil was noticed. In the case of the physician, whose family was attacked after moving into the house which was formerly infected, the permanence of the diphtheritic germ appears to be illustrated. This history of successive outbreaks occurring in one house after the lapse of a long interval is not uncommon.

"The history of the disease in the small town to which I have referred was that of introduction from without, and then of continuous infection from one person to another through the public schools, the unwise visits of inquiring friends, the usual household visits of the grocer, the want of care on the part of the attending physician, and many other similar avenues of communicability."

The foregoing observations are submitted merely as a small contribution to the history of diphtheria. So far as the writer's observations are concerned, they lend weight to the following conclusions:

- (1) That diphtheria is an eminently contagious disease.
- (2) That it is infectious, not only by direct exposure of the sick to the well, but also through indirect media, such as clothing, and other articles that have come in contact with the sick.
- (3) That the certainty of infection is not so great as in the case of some of the other infectious diseases, notably small-pox and scarlet-fever.
- (4) That overcrowding, faulty ventilation, and filthy condition of tenements favors its spread.
- (5) That the influence of defective plumbing is not proven.
- (6) That its transmission through public and private water-supplies is not proven.
- (7) That its propagation is favored by soil-moisture, damp cellars, and general dampness of houses.
- (8) That the poison may remain dormant in houses for a long period.

"What constitutes a Fifth-Disease," a paper read by S. W. Abbott, M.D., at the meeting of the American Public Health Association, at Charleston, S. C., December 18, 1890.

## A CASE OF AMEBIC DYSENTERY.

BY E. PEABODY GERRY, M.D., AND REGINALD H. FITZ, M.D., OF BOSTON.

THE medical profession of this country is greatly indebted to Professor Osler, of Baltimore,<sup>1</sup> for calling its attention to the presence of the amœba coli in the intestine in dysentery and in dysenteric abscesses of the liver. Although Lösch<sup>2</sup> first found, described and named this parasite, Kartulis deserves especial credit for his prolonged study and numerous publications concerning its relation to dysentery.

The frequency of this disease in the tropics and the numerous instances of hepatic abscess there occurring were suggestive that the amœba might be of greater significance in the dysentery of the tropics than in that of the temperate zones. The investigations of Kartulis were made in Egypt. Koch found the amœba in the intestinal wall both in Egypt and India. Dr. Osler's first patient acquired the disease in Panama. A second case reported by Lafleur<sup>3</sup> had been in the tropics, and a third, reported by Simon<sup>4</sup> had also been in the tropics, although in the latter cases a number of years had elapsed between the sojourn of the patients in the tropics and the outbreak of the dysentery. In the fourth of Osler's series of cases, reported by Lafleur,<sup>5</sup> there is no mention of any residence in the tropics.

Apart from the series of cases published in the *Bulletin* of the Johns Hopkins Hospital, there have, thus far, been reported in this country, three cases in Philadelphia, by Stengel,<sup>6</sup> in which amœba coli were found in the stools; one in Cincinnati, by Eichberg;<sup>7</sup> amœba being found in the stools and in pus from the liver, and one in Texas, by Dock,<sup>8</sup> who also found amœba in the intestinal mucus and in pus from the associated hepatic abscess.

The following is added to the series of cases occurring in this country since it represents one wholly confined to a more northern latitude and one in which symptoms of a paracolitis suggested the invasion by the amœba of the tissues outside the intestine, but in its immediate neighborhood.

Miss —, twenty-five years old, had been strong and well till two years ago. She then became pale, somewhat thin and weak, while caring for a sick mother who died with bronchial disease. She recovered her flesh and strength but remained pale. During this time she was in the habit of drinking water accumulated in a cistern which was supplied from rain falling on the roof of the house in which she lived in a neighboring city.

In August, 1890, some two months after leaving this house and after her return from a short visit to the White Mountains, she noticed a whitish, solid discharge from the rectum, resembling a clot. Her bowels, at this time, were constipated, but in the course of a month, occasional discharges of small quantities of bloody mucus were observed in which were numerous white specks and streaks. Discharges of similar character, mixed with more or less semi-solid or liquid, brown feces, and of an offensive odor have since continued, three or four times daily, despite

the use of various remedies, although at one time an interval of eleven days existed without any movement of the bowels. They were painless, unaffected by food or drink and were not accompanied by loss of weight or strength. There was neither nausea, jaundice, tenderness nor tenesmus. There was considerable flatulence, and pallor of the skin was conspicuous. In the summer of 1891 the number of dejections became diminished, especially during a stay at the sea-shore.

In the last week of September, 1891, without any obvious cause, the stools became more frequent, ten to fifteen daily, and were more bloody. At the end of a week the previous character and frequency of the dejections were resumed although the latter became conspicuously more offensive. Tenderness in the right iliac fossa has persisted since this time. A slight loss of flesh now became obvious. She slept well, but lay on her back with the knees drawn up, as a lateral position produced an inclination to empty the bowels. She was then seen by Dr. George W. Gay, in consultation, who agreed in considering her case as one of ulcerative dysentery.

In the last week of October, 1891, the abdomen rapidly became swollen, the tenderness extended upwards from the right iliac fossa towards the liver, just below which it became most marked and was associated with resistance. The temperature rose from the normal to 101° F. and the pulse became 120. There was loss of appetite, drowsiness, slight sweating and frequent micturition. At this time Dr. M. H. Richardson and Dr. Fitz saw the patient in consultation.

The abdomen was then slightly and symmetrically distended, tympanitic everywhere except over a space as large as the palm of the hand at the right of the navel, between the costal cartilages and the anterior superior iliac spine, extending nearly to the median line. The dull region was tense and tender, the resistance gradually lessening towards the edge. There was neither elasticity nor a sense of fluctuation. There was slight tenderness in the hypogastrium just above the symphysis. The liver dulness was slightly increased; there was no tenderness in the hepatic region. The splenic dulness was somewhat increased, the edge of the spleen not palpable. The rectal examination was negative. There was a systolic souffle at the heart's apex and in the second left intercostal space near the sternum. The examination of the lungs showed nothing abnormal. Two stools, seen at this time, were homogeneous, soft, pap-like in consistency. They were of a brown color mixed with red from the presence of blood, and in one were clumps of reddish mucus, translucent, like sago grains.

A diagnosis was made of chronic ulcerative colitis, acute paracolitis and probable amœba coli in the intestine. High rectal enemata of dilute solutions of quinine (1 to 5000) were recommended in consequence of the experience of Kartulis and Osler.

The feces were examined microscopically, at intervals, during a period of several days and amœba coli were always found. They appeared as round, or slightly oval bodies, varying somewhat in size, but, in general, with a diameter six or seven times that of a leucocyte. The periphery often appeared like a homogeneous, hyaline membrane, while the body of the amœba was composed of coarse, gray granules. Within the body a nucleus was often to be seen, also vacuoles, and, occasionally, one or more red blood corpuscles.

The feces were brought from a distance of several

<sup>1</sup> Johns Hopkins Hospital Bulletin, 1890, I, 53.<sup>2</sup> Virchow's Arch., 1875, LXX, 196.<sup>3</sup> Johns Hopkins Hospital Bulletin, 1890, I, 91.<sup>4</sup> Loc. cit., 1890, I, 91.<sup>5</sup> Loc. cit., 1891, II, 83.<sup>6</sup> Medical News, 1890, LVII, 560.<sup>7</sup> Loc. cit., 1891, II, 201.<sup>8</sup> New York Medical Record, 1891, XI, 7.

miles during a period of cold weather, and the amœbæ were invariably motionless, even on the hot stage. In only one instance were pseudopods present, but they remained quiescent during a period of several minutes.

The diagnosis of a paracolis in this case of dysentery was suggested by the acute, febrile attack connected with the limitation of the sudden and sensitive induration to the course of the ascending colon, the absence of a sharply-defined edge, and the failure to appreciate the fluctuation or elasticity which usually accompany an encysted fluid near the abdominal wall. An anatomical basis for this diagnosis is furnished by the evidence given by Dr. Councilman<sup>9</sup> of amœbæ coli in the fat tissue of the meso-colon.

At present, ten days after the onset of the acute attack of fever and abdominal pain, the induration is very much softened and the temperature is normal.

Water which the patient was accustomed to drink was examined microscopically and found to contain small amœbæ in active motion, also a larger, quiescent variety. The latter corresponded in size with those found in the dysenteric stools. Their contents were alike coarsely granular, but were of a markedly green color.

Whatever may be said of the etiological significance of amœbæ coli in dysentery, marked diagnostic value must be attached to their presence. Although the case above reported is one which would be classified under the term dysentery, there were neither painful stools nor painful bowels during the greater part of the time. An ulcerative cæcitis or colitis of malignant or tubercular nature was suggested by both positive and negative evidence. The discovery of the amœbæ coli, in the light of our present knowledge, was almost conclusive evidence in opposition. Kartulis<sup>10</sup> has sought for them, in vain, in hundreds of intestinal cases other than dysentery and has found them in every case of undoubted dysentery and in all hepatic abscesses in dysentery. Osler<sup>11</sup> found them in pus from a hepatic abscess removed during life from a case of dysentery, and he has recently<sup>12</sup> found them in the sputum of a case of suspected pleurisy where there was no diarrhœa, only a little bloody mucus in consistent stools. In this last case the positive diagnosis rested upon the presence of the amœbæ in the sputum.

The accumulating evidence of the constant occurrence of the amœbæ coli in the stools, the intestinal wall and in hepatic abscesses in certain cases of dysentery, renders it highly probable that these amœbæ are of decided importance in the causation of dysentery, especially of the ulcerative variety.

Lösch<sup>13</sup> experimented with the amœbic stools and found that they violently irritated the mucous membrane which became ulcerated and amœbæ were found in the base of the ulcers. Kartulis<sup>14</sup> claims that he has successfully cultivated the amœbæ and by injection-experiments on cats, has proven that the cause of dysentery is to be found exclusively in these amœbæ. These observations require confirmation, but it may be expected in the early future that the etiological importance of amœbæ coli in certain forms of dysentery may be as definitely settled as the diagnostic value of their presence must be admitted.

## Clinical Department.

### INCISION OF A FALSE ILIAC ANEURISM.<sup>1</sup>

BY E. H. BRADFORD, M.D.

A STOUT man, with a history of previous good health, was brought to the hospital with the statement that two weeks before he had strained himself, and experienced considerable pain in the right groin. This pain had increased, and two days before entrance into the hospital he was obliged to lie in bed. He was examined by his physician, and referred to the hospital with the diagnosis of appendicitis. This appeared to be probable from the locality of the pain, and of the resistance felt in the groin. The thigh was flexed, and the patient unable to move, but the patient was not feverish, through restless, anxious and distressed, requiring opiates. The right thigh was somewhat swollen and congested. On palpation a large, indurated mass was felt in the groin, but no fluctuation was discovered, and no pulsation; though palpation was not thoroughly carried out, because of the patient's sensitiveness, which was marked. Under an anæsthetic the condition was very much the same. A large mass of induration was felt in the iliac region, and this was cut down upon in a line an inch above Poupart's ligament. The muscles were found congested, and when the peritoneum was reached, it seemed darker than normal. The incision into the peritoneum allowed a certain amount of clotted blood to escape; and as the wound was enlarged a large clot was pressed out, followed by fresh blood. The nature of the injury was then apparent. The wound was enlarged, the clots were turned out, and a jet of fresh blood about the size of the radial could be discovered issuing from the depth of the wound. Sponges were introduced into the wound to stop the bleeding; abdominal compression was applied, which controlled the bleeding; large abdominal retractors were placed in the wound; and by the use of these the bleeding-point was found at a great depth. This was finally secured by long-pressure forceps, and the bleeding stopped. Attempts, however, were made to tie the bleeding-point, but this was found impossible as the ligature invariably slipped.

Attempts were then made to dissect up the artery, and tie above and below, but this was found impossible. The cause of this was not determined until after death. The bleeding was stopped by means of pressure forceps, the forceps left in the wound and salt transfusion employed. The patient was removed from the table, but died four hours later. On examination the following condition was found: A true aneurism was discovered, arising a short distance below the bifurcation of the aorta (three-fourths of an inch), extending down to a short distance above the femoral, the internal iliac issuing from the aneurismal sac. This had ruptured, forming a large false aneurism, with the existence of clot, which had presented in the inguinal region, giving the appearance of inflammatory product. The bleeding-point was from the rupture of the sac; this was comparatively small and at the upper part of the sac. It was, of course, impossible to tie the artery; for the artery was not a simple vessel, but the sac of an aneurism, extending nearly to the aorta — beyond surgical reach.

The case is of interest, and needs to be recorded

not only because all serious errors in surgery, as well as successes, should be reported, but also because the case demonstrated the feasibility and ease with which the upper part of the common iliac could be reached by surgical intervention. It also illustrated with what ease the hemorrhage was controlled by manual compression of the aorta, through the abdominal wall.

### BULLET WOUND OF THE SKULL.

BY E. H. BRADFORD, M.D.

AN unusual course of a bullet is illustrated by the following case:

The patient was a man twenty-two years of age, who entered the hospital January 17, 1890, with a small pistol-shot wound in the right fronto-parietal region. There was a slight amount of swelling of three quarters of an inch in front of the punctured wound. The pistol had been discharged with suicidal intent, and the hair was singed. On probing the wound, the opening into the skull could not be found, and the bone only was touched. The patient was conscious, and all motions were good; but the right pupil appeared to dilate more rapidly than the left. The pulse was ninety, and there was no shock. The patient had some headache, but otherwise was in good condition. Two days after entrance the patient was etherized, and a curved incision was made over the wound and the flap reflected. A small fragment of a bullet was found under the skin, corresponding to the swelling that was felt; and a fragment of the outer table, of the size of a five-cent piece was removed, with the bullet-hole in the centre. Under this was found, lying in the fragment of the inner table, a misshapen bullet, which was lying with the butt-end close to the dura. The bullet had struck the skull, had fractured the outer table, had fractured the inner table, and penetrated the inner table. It had turned a half-revolution, so that its butt-end lay on the dura. The bullet was removed, and a complete perforation of the bone down to the dura discovered, but without wound of the dura. The patient made a rapid recovery.

The case illustrates the lack of reliability of the probe as a means of exploration, without preliminary trephining, as the position was not discovered until after dissection of the flap of the skin covering the wound. It also shows the remarkable fact that a pistol of good size, placed against the parietal region, may penetrate the skull without penetrating the dura, and leaving the bullet in contact with the dura with — what is still more remarkable — a complete revolution of the bullet in nearly its own axis from the point of impact to the point of rest.

### A CASE OF SEVERE VOMITING OF PREGNANCY.

BY EDWARD G. OTIS, M.D., BOSTON.

On September 27th of the present year I was summoned out of town to see Mrs. S., in consultation. I found her in bed constantly vomiting and retching, with accompanying nausea and pyalism. Her suffering and distress were painful to witness, and I was vividly reminded of a terrific day of sea-sickness.

I had recently experienced on the German Ocean. This was her second experience with severe vomiting of pregnancy, and before giving the details of this case I will narrate the previous one as she told it to me.

About three years ago she was married for the first time, being about eighteen or twenty years of age. Not long after her marriage, while in Southern California she received a severe nervous shock, having at that time passed a catamenial period by three weeks. Immediately upon this she journeyed to San Francisco, her home, and in a couple of days after her arrival began to feel indisposed. After three or four days' confinement in bed, nausea and vomiting began, and continued, with ever-increasing violence for a week. At the end of that time a consultation was held and an examination made. The urine was found to be highly charged with albumen, and the uterus retroflected; in the words of the patient, "It had fallen back upon the kidneys." The temperature was said to have ranged from 101° to 104° F. From this time forward she was nourished by nutrient enemata of milk and brandy. The vomiting and nausea continued, violent and distressing; and three weeks after it first began a sponge tent was introduced into the os with the intention of producing abortion. This was repeated on the following day, and several hours afterwards, on assuming the upright position, the abortion occurred. The nausea ceased at once, and she was able to take nourishment by the mouth. The albumen in the urine rapidly decreased. The convalescence was slow, and it was not until about five months after the beginning of the catastrophe that she was well enough to be placed upon a steamer and sent down the Pacific coast on a cruise. She weighed at the time but seventy pounds. She gained rapidly, and a few days out was able to walk, and in a month's time, at the expiration of the voyage, she was nearly well.

Her husband died soon afterwards, and she remained a widow until the winter of 1890-91, when she married again, not deterred by this painful experience of the former matrimonial venture. All went well until the seventh of last September, when the catamenia, which was then due, remained absent. She was in the country at the time, and in the best of health. A little later she went to New York, and after considerable exertion and fatigue she first began to have nausea. This was on the seventeenth of the month. She returned to her home at once, the nausea increasing and the vomiting beginning. She kept about, however, until the twenty-second of September, when she took to her bed, the nausea, vomiting and retching being then almost continuous and very distressing. Her physician tried many remedies, cocaine, menthol, pepsine, bismuth, oxalate of cerium, chloroform, water, etc., but of no avail. When I saw her for the first time, on the twenty-seventh of the month, she presented a pitiful picture, vomiting or retching continually, and constantly harassed with pyalism and thirst. On vaginal examination I found the os far back in the left posterior corner of the vagina, and the uterus, so far as I could make out, laterally ante-flexed. The os was small and firm. There was no rise of temperature at this or any time during her illness; on the contrary, it was a good deal of the time slightly below normal. The daily amount of urine was much reduced, ranging from 5v + to 5xxviii +. There was no albumen. The pulse was fair and between 80 and 90. She was having enemata of peptonized milk and brandy every four

<sup>1</sup> Read before the Boston Society for Medical Improvement, October 12, 1891.

hours, and from time to time subcutaneous injections of morphia and atropia. She would sleep or doze occasionally an hour or two at a time. The experience of her previous pregnancy was vividly before her mind, and she was convinced that nothing would relieve her except the production of an abortion which she was eager to have consummated, and in which desire her husband concurred.

Our first attempt was to paint the os with tincture of iodine which was without result, as was also the application of belladonna. I then essayed to dilate the os by means of improvised dilators—none others being at hand—digital dilatation being impossible on account of the depth of the cervix uteri in the vagina. In this attempt I was, however, not very successful, on account of the rigidity of the os. I applied a tampon, and advised warm bichloride douches daily, which were given. At this time and subsequently considerable mucus, occasionally tinged with blood, was found exuding from the os. No amelioration of the symptoms following, and the condition seeming alarming, the next attempt was to produce an abortion by the passage of a sound, and then of a catheter, which was allowed to remain *in situ*, but with no success; probably neither was passed fully into the uterus. She was by this time weak and exceedingly nervous, and any manipulation was difficult.

On the following Sunday, October 4th, about two weeks from the beginning of the attack, a large Tupelo tent was passed well through the outer os, and allowed to remain there a greater part of the day. This effected a thorough dilatation. Nausea ceased almost at once, and she felt as if she could eat something; but the vomiting still continued, and it was not until three or four days later that she was able to retain some nourishment.

On Tuesday, October 6th, she was given along with the nutrient enemata, forty grains of bromide of potash and fifteen of chloral hydrate, twice or three times in the twenty-four hours for a day or two, and after that once at bed-time. The subcutaneous injections of morphia and atropia were also continued. On Friday night, October 9th, she vomited for the last time, and in a day or two was eating with relish a variety of food.

Four weeks after she first went to bed, she sat up for the first time. For seventeen days she had vomited almost continually. So far as could be estimated, she had lost from fifteen to twenty pounds of flesh. At the present time, some seven weeks from the beginning of her sickness, she is entirely free from nausea and vomiting, and eats well. Everything seems to indicate a comfortable pregnancy; and both the physicians, patient and husband are congratulating themselves that the attempt to produce an abortion was not successful.

I have reported this case because I believe the experience with every severe case of pregnancy vomiting is valuable enough to be recorded. Surely, but few cases occurring in general practice give the physician so much anxiety as these. What was the cause of the vomiting in this case, and what produced the cure? The cause, in my opinion, was the reflex excitement from the irritation of an ante-flexed pregnant uterus, with more or less rigidity of the tissues of the cervix. That the full dilatation of the cervix had much to do with the cure is undoubted, for the nausea ceased at once, although the vomiting continued several days longer. When we consider the success Copeman had

with this procedure, perhaps it was the sole cause. Whether or not the bromide and chloral given the last few days of the vomiting exercised any favorable influence I cannot say; it seems to me, however, that they helped on a good work already begun by the dilatation. In such severe cases all attempts at medication by the mouth seems to me to be worse than useless. Copeman's dilatation treatment, replacement and elevation of an ante-flexed or retroflected uterus are what must be depended upon, it seems to me, if a cure is to be obtained at a less cost than the induction of abortion.

## PTYALISM IN FIVE SUCCESSIVE PREGNANCIES.

BY BARTON COOKE HIRST, M.D.

Mrs. F. has been married four years, and is pregnant for the fifth time. The previous pregnancies have all been artificially interrupted for ptyalism and vomiting, the first at the fifth month, the others before the third month. The patient states that these symptoms have appeared within a few days after impregnation, and that they reduce her strength to the last degree. She is firmly convinced from past experience that she could not survive a pregnancy protracted beyond the first two or three months, and her husband shares her belief. The saliva is poured out from the glands profusely, and must be swallowed in large amounts or else expectorated constantly. The nausea and vomiting seem to be secondary to the ptyalism. They are exaggerated, but not to a degree that could be called pernicious or uncontrollable.

The woman has an idea, suggested by her husband, that the excessive secretion of saliva can be to some extent controlled by chewing gum candies, which she does day and night, going to bed with a box full by her side. She is, of course, highly hysterical.

On examination, the uterus was found normal in size, consistency and position for the second month of pregnancy; it was freely movable, and there was no trace of inflammatory action, old or recent, in the broad ligaments. I was called in consultation to the case, with the expectation on the part of the family, that I would at once induce abortion. This I refused to do, as the woman's life was in no danger whatever. I expressed the opinion that a rigid discipline and a modified "rest cure" would very likely get the better of the hysterical symptoms and possibly of the ptyalism, and that pregnancy could be continued to term without special danger. This opinion was evidently unacceptable to the wife and the husband, and I have no doubt that by this time other medical advice has been sought and that the embryo has been sacrificed.

It is generally conceded that marked salivation in pregnancy is an infrequent occurrence. Its recurrence in a number of successive pregnancies seems to be very rare indeed. Baudelocque described a case which is referred to by Winkel, who does not appear to have encountered a similar instance in his large experience. Other modern obstetrical works are silent on the subject.

In a recent lecture Professor Billroth spoke on the effect of the new rifle in war, and declared that the ambulance department in Austria would be absolutely inadequate to deal with the vast number of the wounded.

## Medical Progress.

### RECENT PROGRESS IN THERAPEUTICS.

BY FRANCIS H. WILLIAMS, M.D.

(Concluded from No. 22, page 572.)

#### SUBCUTANEOUS INJECTIONS OF CARBOLIC ACID IN ACUTE ARTICULAR RHEUMATISM.<sup>8</sup>

In 1875 Senator published a paper in which he pointed out that marked alleviation of the local and some amelioration of the general symptoms quickly followed the subcutaneous injection of a strong solution of carbolic acid into the neighborhood of the affected joints. This was accomplished without any appreciable ill effects to the patients.

Dr. A. L. Gillespie has tried this treatment in twenty-four cases and publishes notes of five of them. He injected from four to ten minims of a ten per cent. solution (?) of carbolic acid. [As carbolic acid is not sufficiently soluble in water to make a ten per cent. solution, some other solvent must have been added to the water.—*REL.*] A grain of the pure acid can be given at a dose.

In some cases relief is speedily afforded and the patients often begged for a repetition of the injection when another joint became painful.

It is said to be of special value in cases of gonorrheal rheumatism in which no relief has followed the use of salicylates, but does not seem to act so well when many of the joints are affected.

It is best to pass the point of the hypodermic needle through the skin obliquely and judging where the synovial membrane is to inject the fluid as close outside the sac as possible.

Injected into the sac itself a ten per cent. solution of carbolic acid precipitates the albumen present in its serous contents.

The rationale of the rapid disappearance is, first, that it is due to the powerful, local anesthetic action of the acid; secondly, to some slight specific action against the rheumatic poison exerted by it.

#### WHOOPIING-COUGH TREATED BY ATOMIZATION.<sup>9</sup>

Dr. H. Ernest Schmid states that he now relies entirely upon atomization for the treatment of whooping cough in all stages of the disease. The spray which he uses is made up as follows:

R Carbolic acid . . . . .	grs. vi.
Menthol, 1% solution . . . . .	3 iv.
Cocaine, 3% solution . . . . .	3 ij.
Glycerine . . . . .	3 i.
Cherry laurel water, q. s., ad.	3 i. M.

This solution should be thoroughly used, brutally, if necessary, by an atomizer every three hours; force may be employed if necessary, and disregarding any apparent strangling upon the part of the little one during vigorous atomization, the nozzle of the instrument should be directed as far into the mouth of the little one as possible. During the struggling and sputtering and strangling some deep respirations will before long be made, and the object is accomplished. At first, in most cases, a violent paroxysm of coughing may result from the spraying, especially if much force has to be used with the child, but these soon cease and palpably good effect is soon noticed by the parents. The point is to be able to impress the importance of

perseverance on them. Dr. Schmid has seen whooping-cough arrested by this means after one thorough spraying, the cough continuing without the whoop for a while, and perfect recovery has followed in one or two weeks. From his success he feels justified in claiming that the method promises to be more efficient than other methods of treating the disease.

#### USE OF PURE BENZOLE IN WHOOPING-COUGH.<sup>10</sup>

Dr. W. Robertson, after some years' experience with the use of benzole in whooping cough, is satisfied that it effects better results than all the other remedies recognized as useful in this affection. In adult and child it is of equal benefit. In an infant just now under treatment the attacks had been reduced from twenty or thirty in the night to two or three, and whereas when the treatment was begun evidences of bronchitis were present, now the chest is clear, and the child able to be taken out of doors daily. All this improvement was brought about in less than ten days. In cases where convulsions and other complications were fast reducing all chance of recovery, its use was attended with perfect success within a few days. In adults, where pertussis assumes often serious aspects, benzole has proved equally efficacious. Two minims in mucilage are sufficient for a child six months old, and five minims in mucilage, on sugar, or in capsule, for adults. Whenever the benzole odor is observed in the breath of the patient, then all anxiety as to the result may be allayed.

#### COMMON THYME IN WHOOPING-COUGH.

Common thyme, which was recommended in whooping-cough three or four years ago by Dr. S. B. Johnson, is regarded by Dr. Neovius, who writes a paper on the subject in a Finnish medical journal as almost worthy of the title of a specific. During an epidemic of whooping-cough he had ample opportunities for observing its effects, and he came to the conclusion that if it is given early and constantly, it invariably cuts short the disease in a fortnight, the symptoms generally vanishing in two or three days. They are liable to return if the thyme is not taken regularly for at least two or three weeks. He gives from one ounce and a half to six ounces per diem, combined with a little marshmallow syrup. It may produce a slight diarrhoea; it is important that the drug should be used quite fresh.

#### SUBCUTANEOUS INJECTIONS OF STRYCHNINE IN TEN CASES OF CHRONIC ALCOHOLISM.<sup>11</sup>

Dr. Ergloski has published an account of ten cases of chronic alcoholism among his patients. They had the habit of taking brandy. They were given subcutaneous injections of nitrate of strychnine, one sixtieth to one twentieth of a grain at each injection. After a dozen injections the results were remarkable as they all acquired a distaste for brandy. In such cases as are desirous of being cured this treatment may prove to be of assistance.

#### IN ACUTE BRONCHITIS.<sup>12</sup>

A simple expectorant mixture in acute bronchitis is:

R Ammon. murat. . . . .	3 ss.
Mist glycyrrhiz comp. . . . .	3 iv.

Sig. Take a teaspoonful every four hours. The dose is smaller in the extreme of life, and in severe cough it is given every three hours.

<sup>8</sup> *Lancet*, vol. vi, 1891.

<sup>9</sup> *Bu. Jett. Général de Thérapeutique*, No. 20, 1891.

<sup>10</sup> *Thérapeutique Gazette*, July, 1891.

<sup>11</sup> *Medical Press*, 1891, No. 129.

<sup>12</sup> *Medical Record*, June 13, 1891.

Tablets of the muriate of ammonium and the compound liquorice mixture are very efficient. When the secretions are brought up with difficulty, the use of senega is advised. When the secretions are abundant and not easily coughed up, turpentine in emulsion is an excellent remedy, not so pleasant, perhaps, as terebene or terpine hydrate, but rarely failing to do good in properly selected cases. The formula, with occasional modifications to suit particular cases, is:

R. Ole. terebinthin . . . . . 3 ij. to 5 ij.  
Mucil. acetos . . . . . q. s.  
Ag. c. manonini . . . . . q. s.  
Aqua, q. s., ad . . . . . 3 iv M.  
Sig. A tablespoonful in a little water every four hours.

Oftentimes the cough is of such an irritating character that these ordinary expectorant mixtures avail little; then recourse must be had to a narcotic in some form. Codeine, a very useful alkaloid of opium, has the advantage of not constipating as much as morphine.

A good combination is:

R. Codeinæ sulphat. . . . . grs. viij.  
Syr. prun. virginian. . . . . 3 ij. M.  
Sig. A teaspoonful in a little water three or four times a day, and at bed-time if necessary.

#### ALOIN.

Prof. Hans Meyer, of Marbury, has examined chemically and physiologically the aloin obtained from various kinds of aloes. From the Barbadoes and Curaçoa he obtained the same crystalline substance. Natal aloes yielded a somewhat different aloin. In experiments on animals and on man the aloin was given *per os*, and also subcutaneously. The aloin can be detected in the faces and urine by tests, which are given at length and which are extremely delicate. Experiments showed that aloin acted with certainty as a purgative, whether given by the mouth or subcutaneously. The dose in both cases is about the same, which is explained by the fact that aloin, when given subcutaneously, is excreted from the blood chiefly into the bowel, only a mere trace, or none, being found in the urine. In man, dogs and cats there is no albuminuria after subcutaneous injection; but in rabbits, in which animal aloes does not cause purgation, subcutaneous administration is always followed by inflammation of the kidneys, albuminuria and death. Its purgative action is as slow when it is given hypodermically as it is *per os*. Natal aloin by subcutaneous injection is always active. In man, on an ordinary mixed diet, it had but little effect, but in man fed exclusively upon an animal diet, it was much more active. The reason probably is that in the latter case the putrefactive processes in the intestine are much more marked, and the aloin is decomposed into a more active substance. All the experiments seem to point to the conclusion that aloin itself is not an active purgative, but that it becomes gradually decomposed in the intestine into a more active body, and hence the slowness of its action.

#### OPiates IN ACUTE PERITONITIS.<sup>13</sup>

Dr. Stephen Smith directs attention again to the importance of large doses of opium in treating acute peritonitis.

Under Prof. Alonzo Clark's direction, he treated six cases in 1810. The patients were seen every hour, the pulse and respiration closely watched. The quantity of opium was to be determined by the effects produced, not at all by the amount administered. The

condition to be secured was that of semi-narcotism; this was to be determined by the degree of stupor and the respiration; the patient must require to be shaken to be aroused to consciousness; and the respiration might fall to twelve per minute, but not below that figure.

At the outset each patient received one grain every hour for three doses. No effect being perceptible, the dose was increased to two grains every hour, and continued for three doses. Failing with this dosage, the opium was increased to three grains every hour. In four cases this amount of opium had the desired effect, and it was continued in that amount. In the remaining cases it had to be increased to four grains every hour. One of these remaining cases yielded to this amount, and the opiate was continued at that rate.

The sixth case was much more obstinate, and the opium was steadily increased until the dose reached was twelve grains every hour. This amount simply secured a light, but continuous, sleep, from which she readily awoke on placing the hand upon her wrist to examine her pulse.

The first four cases continued to receive three grains of opium every hour for three or four days, when the pulse fell to its normal standard, the tympanites subsided, the tenderness of the abdomen disappeared, and the patients were evidently convalescent. The opium was discontinued; they rapidly recovered and remained well.

In the fifth case, on the fourth night the patient was given so much opium, four-grain doses, that she was too deeply narcotized; she was without pulse, pale, and with only four respirations per minute. Active measures were taken to recover the patient from her profound narcotism. After several hours of continuous effort she was regarded as securely restored. All symptoms of peritonitis now rapidly subsided; the pulse had fallen from 112 to 92 per minute, the tympanites and tenderness had disappeared, and she expressed herself as feeling well. Within twenty-four hours all evidences of peritonitis recurred, and the treatment was renewed, three grains of opium being given instead of four. Semi-narcotism was readily produced, and after a brief period the symptoms again subsided; the treatment was suspended, and she was perfectly cured.

The sixth case proved an anomaly in tolerance of opiates. During twelve days the treatment was persevered in, the pulse remaining at about 120, the respirations 34-36, the abdomen greatly distended and tender to the touch, lancinating pains, the features pinched, perspiration at intervals, etc. During these twelve days the patient took the equivalent of 1,350 grains of opium, and she neither vomited during that time nor had an evacuation from her bowels. At no time was she so narcotized that she would not awaken when a hand was placed upon her wrist. She remained in the hospital as an assistant in the laundry for six months after her recovery, and during that time was an excellent help.

Professor Clark thus describes the method of medication: the plan is to begin with a dose that is safe, say two or three grains of opium, or its equivalent of sulphate of morphine, and in two hours notice its effect. If any of the opium symptoms have appeared, repeat the dose; if not, increase by one grain, and so on, at intervals of two hours, till the degree of tolerance in the patient is ascertained. After that the case

<sup>13</sup> Medical Record, vol. xxxix, No. 22, 1891.

can be treated by a diminished occupation of the physician's time—two or three visits a day. The dose is to be increased if the opium symptoms diminish, or discontinued if narcotism is approaching. The duration of the treatment will be sometimes no more than two or three days; it may be a week, or even a fortnight; and in one case the symptoms persisted mildly for forty days, and then yielded.

In this case the medicine used was sulphate of morphine, and the enormous dose reached, by steady and gradual increase, was one grain and a quarter every forty minutes, in a boy ten years old.

Of the several signs of opiumism, there is none more valuable than the frequency of the respiration; and while the physician aims to reduce it to twelve in a minute, there are chances that he will see it fall to something below that. Professor Clark does not explain the curative action of opium in peritonitis, but Prof. Fordyce Barker, who had a large and varied experience in puerperal peritonitis in Bellevue Hospital, considered opium the most important of all agents in arresting and controlling this disease. By it the peristaltic movements are retarded or arrested, and thus the inflamed tissues have absolute rest, pain is annulled, emotional excitement is allayed, the nervous system is tranquilized, sleep is secured, and thus the depression of the vital forces resulting from the shock of the attack is lessened.

#### CORROSIVE SUBLIMATE AS A DISINFECTANT.<sup>14</sup>

Experiments published by Dr. A. C. Abbott, made in the Pathological Laboratory of the Johns Hopkins Hospital, have a very practical bearing upon the value of corrosive sublimate as a germicide, and the results of these experiments lessen the high estimation in which this agent has been held by the majority of investigators.

Dr. Abbott selected the staphylococcus pyogenes aureus for a series of experiments as to germicide power in consequence of the importance of the subject to the surgeon.

The tests hitherto made upon corrosive sublimate as a disinfectant have agreed in giving to it the first place in the list of these agents.

One method commonly employed in testing the value of any chemical substance as a disinfectant is to expose organisms dried upon bits of silk thread to its action for different lengths of time, and then, after removing and carefully washing the threads in alcohol, to place them in nutrient media at a favorable temperature and notice if any growths result from them. If no growth appears, the disinfection was presumably successful. Another common method is to mix fluid cultures of organisms with the disinfectant, and after different intervals of time, a portion is taken from the mixture and placed in nutrient media just as in the other method.

Now, in both of these methods it is easy to see that unless special precautions are taken, a minute portion of sublimate may be carried along with the thread or drop into the medium which is to determine whether or not the organisms on the thread or in the drop, still possess the power of growth. For organisms in their normal condition, that is, those which have never been exposed to the action of a disinfectant—the amount necessary to restrain growth of certain disinfecting agents, is very small indeed; and for those

organisms which have previously been exposed for a time to such agents, Geppert shows is very much less. In case of the organism we are considering, Dr. Abbott finds the amount of sublimate necessary to prevent the growth of perfectly normal staphylococci, to be one part of sublimate in 75,000 of the ordinary peptone bouillon, or 200,000 parts of bouillon without peptones. So that, if organisms which have been once exposed to stronger solutions of this salt (1-1000) require less than these amounts to inhibit their growth, it is plain that special precautions must be taken to prevent transportation of a minute trace into the nutrient medium which is to demonstrate whether or not the organisms are capable of development.

The author gives in detail the series of experiments, and draws the following conclusions:

That, under the most favorable conditions, a given amount of sublimate has the property of rendering inert only a certain number of individual organisms—that is to say, the process is a definite chemical one taking place between the protoplasm of the bacteria and the sublimate in the solution.

The disinfecting activity of the sublimate against organisms is profoundly influenced by the proportion of albuminous material contained in the medium in which the bacteria are present. It was found that the relation between the golden pyogenic staphylococci and sublimate is not a constant one. Organisms from different sources and of different ages behaving differently when exposed to the same amount of the disinfectant for the same length of time.

Many of the results of previous experimenters, who have assigned to corrosive sublimate more powerful disinfecting properties against the staphylococcus pyogenes aureus in cultures, than the observations reported in this paper indicate, are attributable to the neglect of certain precautions now recognized as essential to the proper conduct of such experiments.

At the present stage of our knowledge in this direction, it is plain that for use in surgical practice, the solutions of corrosive sublimate do not possess all the advantages hitherto attributed to them.

In regard to the employment of sublimate solutions upon wound surfaces, it is plain that there exist at least two serious objections; first, the albumen of the tissues and fluids of the body tends to diminish the strength of, or, indeed, renders entirely inert the solution employed; and, second, the integrity of the tissues is materially injured by the application of this salt. The first objection cannot be met with certainty, for the surgeon possesses no means by which he can determine the amount of albuminous material with which his solutions are to come in contact, and in any case this large amount of albuminous material is an almost inseparable obstacle to complete disinfection with sublimate. He is, therefore, never in a position to say, *à priori*, that his efforts at disinfection of the wound are, or are not, successful.

During the past two years we have had sufficient evidence to lead us to believe that the normal tissues and fluids of the body possess the power of rendering inert many kinds of organisms which may have gained access to them. This function is therefore diminished, or, indeed, may be quite destroyed, by any agent which brings about alterations in the constitution of these tissues. We know that just such changes as those to which we refer are known to follow the application of sublimate solutions. It is plain, then, if we bring

<sup>14</sup> Johns Hopkins Bulletin, No. 12, 1901.

about in these tissues a condition of superficial necrosis—the condition following upon the application of sublimate—they are much less able to resist the inroads of infectious organisms than they would have been had they been left in their natural condition.

As a disinfectant, in the strict sense of the word, there are, perhaps, few substances which possess the property in a higher degree than does corrosive sublimate, but, at the same time, there is nothing which is employed for this purpose that requires greater care in its manipulation, in order to obtain its best results, than does this salt. In practice, its action is influenced by a number of conditions which it is difficult, if not quite impossible, to control.

For these reasons we seem hardly justified in continuing to give to it the first place in the list of substances which may be employed practically for the purpose of rendering harmless, materials containing the germs of infectious maladies.

#### METHODICAL EMPLOYMENT OF SULPHONAL IN MENTAL DISEASES.<sup>15</sup>

Dr. Forster publishes his medical experience with fifty-six patients of the Königsmutter Institution and he was much pleased with the result. The drug acted principally as a motor depressant, noisy, obstreperous patients were quieted; many who were given to soiling themselves ceased to do so. This condition of restfulness was induced in excitement stages of acute and chronic insanity, periodical and chronic mania, senile dementia, progressive paralysis, idiocy, epilepsy. Thirty grains were generally sufficient, but as much as sixty were sometimes given. A single dose was from seven and a half to fifteen grains; in periodical excitement, given continuously, it shortened and ameliorated the period of excitement; and it was of special value in cases of acute melancholia and insanity. Epileptic attacks were not so violent; a cure of epilepsy was not achieved.

He observed two forms of by-effects, called by him sulphonalismus, the first was a motor and sensory depressive form, but appeared as parietic weakness, at first, of the lower extremities, then of the tongue and upper extremities. The other form was a persistent somnolency and a diminution of sensation, weakening, or extinction of the cutaneous sensibility. The first stage of this was not dangerous, but the second required careful observation. The symptoms disappeared quickly on reduction of the dose of sulphonal. The pulse was generally regular and strong. Neither respiration nor the uro-genital system was injuriously affected. Disturbances of the digestive tract were, however, observed twice with an exanthem. Tolerance of the drug was never observed, so that, unlike morphine, it can be discontinued at any time.

#### TOXIC DOSE OF OIL OF TURPENTINE.<sup>16</sup>

The daughter of a former Hawaiian missionary states that the natives of the Islands are so fond of drink that the native house-painters will drink oil of turpentine for its intoxicating effect when they are unable to obtain any other stimulant. They have been known to drink as much as a pint at a time. From this statement it would appear that the toxic dose of this substance is far beyond any dose dreamed of by therapeutists.

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, October 12, 1891, the President, DR. FREDERICK J. KNIGHT, in the chair.

DR. E. G. CUTLER reported

#### SOME CASES OF GASTRIC DILATATION.<sup>1</sup>

DR. F. C. SHATTUCK: The interesting cases so well reported by Dr. Cutler certainly justify his statement that gastric dilatation is not recognized as often in these parts and as early as it should be. The important fact is also brought into prominence, that extreme dilatation very frequently does exist without the copious vomitings supposed to be more or less characteristic of the condition before the stomach-tube came into general use, even without vomiting at all. One of the cases, that seen with Dr. Boland, was seen by me a year before he consulted Dr. Cutler. His stomach must have been dilated at that time but I did not detect it for some reason or other. The soft stomach-tube renders a diagnosis possible in many cases in which, without its use, an accurate diagnosis could not be made; and, for treatment, the tube is indispensable. There is much that is disappointing in the results of a vast deal of work devoted to the stomach and its diseases of late years and the chemical examination of the gastric contents has not yet borne the fruit which was hoped for. But the diagnosis and treatment of dilatation has been enormously furthered.

In one of the cases reported, a long interval elapsed between the ingestion and the expulsion of a certain article of diet. In one of the first cases of this condition which came under my observation, the dilatation was very marked and gastric peristalsis was visible through the abdominal wall; the presumable cause was hypertrophic stenosis of the pylorus. She would never consent to the use of the tube and by very careful diet and rest alone great improvement was gradually seen. She became so comfortable that she indulged in canned corn, a considerable quantity of which was vomited a fortnight later quite unchanged.

In another case of great dilatation with visible peristalsis a much longer interval elapsed. She was under my care two years ago at the Massachusetts Hospital and my attention was called to some peculiar looking masses in the washings of the stomach the first time the treatment was instituted. Careful examination showed these fragments to be pear-kernels and it was found that nothing of the kind had been swallowed for upwards of four weeks, when she did eat one pear. Pieces continued to come away with almost every washing until the forty-sixth day after the pear was eaten when the last was obtained. This case was of great interest etiologically. She had suffered from attacks of bilious colic for many years and during 1887 and 1888 was laid up for many months by a succession of abscesses discharging outward over the site of the gall-bladder, but finally healing completely. Her stomach symptoms dated from this time and there can be but little question that pyloric or duodenal stenosis was caused by the cicatrix of the ulceration set up by gall-stones. The usual gain in comfort and strength followed lavage and diet and has been maintained up to the present time.

<sup>1</sup> See page 585 of the Journal.

<sup>15</sup> Medical Press, 1891, No. 2730.

<sup>16</sup> New York Medical Journal, 1891, 28.

In these cases of dilatation following stenosis the dilatation may be notably diminished by appropriate treatment, although the essential cause persists. Lavage enables us to prevent the distending forces of large fluid accumulation and gaseous decomposition; and the wall of the living stomach is not quite like a rubber band which, when once overstretched, is incapable of repair. I have encountered one or two cases in which it was impossible to satisfactorily inflate the stomach, presumably because the pylorus failed to contract and the air could thus pass freely into the intestines. I should be glad to hear whether Dr. Cutler has also seen such cases, and, finally, should like to endorse to the full all that he has said in his important paper.

Dr. A. L. MASON: I have little to add to what has been already said. I have been much interested in Dr. Cutler's cases, and think he is to be congratulated on the successful result of treatment. At the City Hospital I have seen a few cases of dilated stomach, less in extent than those Dr. Cutler has reported, and the treatment by washing out has been brief. The patients have disappeared, and I have been at a loss to know how far it was remedial. It seems to me that where such enormous dilatation exists, due to an atonic state of the muscle, the condition must probably recur soon after the patients escape notice or stop treatment, and I would like to ask Dr. Cutler whether his patients have been able to continue the treatment at home.

Dr. CUTLER: One of these cases passed the tube the second time, remained at the hospital a few days, went home and has been using it ever since. Another patient, the plumber, has been using it every three or four days for over a year himself. When he feels pretty well he leaves it off, taking it up again when the symptoms get rather bad. I have one patient who has been following up the treatment more or less regularly for four or five years.

Dr. MASON: That seems to be a sufficient length of time in that particular case, but the treatment is rather recent, and I suppose the dilatation occurs as a rule in rather feeble persons, debilitated more or less, at middle age perhaps, and, of course, curative results cannot be altogether expected, especially as in many instances there may be some form of organic stenosis. However, that does not make the condition any the less interesting, or the result of treatment less satisfactory.

I would ask Dr. Cutler also, whether he has seen any dangerous symptoms or any great difficulty in passing the tube, because I was present in one instance where suffocation seemed imminent from the regurgitation of fluid around the tube into the trachea, so that the tube had to be withdrawn. It was in a feeble person who may have had malignant disease, but the condition seemed dangerous.

Dr. J. C. WHITE: Will Dr. Cutler explain the significance of his remarks, in connection with two or three cases, with regard to the quantity of hydrochloric acid present. To one ignorant of the subject it did not convey anything. I would like to ask whether it was normal or abnormal.

Dr. AMBOTT said, he would like to ask whether the process of washing out the stomach, in all its details, is entirely free from danger. Recent severe accidents from the injection of water into the intestines for the purpose of overcoming intussusception, — such as rupt-

ure of the bowel, and in some instances cracking of the mucous membrane without complete perforation, — suggest the importance of extreme caution in washing out the stomach to avoid the occurrence of similar accidents. It would seem that the quantity of water employed, as well as the height from which it is poured, should be points carefully to be considered in these cases.

Dr. BROUGHTON: I think Dr. Cutler did not allude to the etiology of the cases.

Dr. FIRZ: I remember seeing one of Dr. Cutler's cases, a case of distension visible to the naked eye, and the muscular contractions excited by tapping on the stomach could be seen. In reference to the subject in general, I have nothing to say.

Dr. F. C. SUATTUCK: I would like to ask Dr. Cutler whether he has encountered any cases in which it was impossible to inflate the stomach, owing to insufficiency of the pylorus, the gas passing directly outward into the intestine; and if so, how common they are.

Dr. E. G. CUTLER: I recall that once. I do not remember ever seeing it at any other time.

In reference to Dr. Mason's remark in regard to the age of these people, it so happens that almost all my cases were young. One, I believe, was forty-six years of age.

With regard to the prognosis, I take it for granted that it depends upon the underlying cause. If this be a cicatricial stenosis, it is not going to be removed by washing out the stomach. The condition will persist until the patient dies, or until either the Loretto operation is performed and the patient dies from that, or until some other operative interference, as an anastomosis between the stomach and intestine or some such thing, is performed. The mortality from such operations is so great at the present time that it seems inadvisable to do anything of that sort unless forced to; and the person usually is very comfortable, gets along very well with the washing treatment, and there are cases on record where washing has been done for a large number of years with the greatest success. It is a nuisance, of course, to put a stomach-tube down the throat occasionally and wash out the stomach, but that is about all.

With reference to the dangers or difficulties in passing the tube, I have read of them, but never saw anything of the kind whatsoever. It has always been my habit to select a tube suitable to the patient, just as I would not undertake to put a number-six shoe on a number-twelve foot. Usually I have taken rather a smallish tube. I have had the patients vomit now and again, not very frequently, but I never saw any difficulty whatever. Occasionally the patient does vomit several times (two or three); but if you instruct him, — at least it has been my experience, that if you hold the rod of authority over him, and tell him how to breathe and act and hold his head, and put the tube not too far down so as to irritate the stomach, it has been my good fortune thus far to be rather free from attacks of vomiting. When you first start off, the patient is very apt to vomit once if there is a very considerable amount of dilatation, because he has got too large a quantity of stuff in him and the slightest irritation is apt to set it a-going. But I have seen no danger from it. I have, however, seen a great deal of discomfort arising from the irritating character of the vomitus on the tongue, mouth, lips and the oesoph-

phagus, from the long continuance of the œsophageal or the stomach-tube in its place, so that this nasty stuff has been enabled to act some little time on the parts. It is rather more frequently the case, if you are too long at the first washing, to have a good deal of soreness as the result. That is the only discomfort I have ever seen.

With regard to the presence of hydrochloric acid in the gastric juice, in the healthy stomach after digestion has been fairly established it is a normal thing to have a certain amount of free hydrochloric acid. There are certain conditions in which it is not found, and those are cases where the pyloric end is diseased to such an extent that many of the peptic glands have undergone degeneration or there has been loss of substance from ulceration or new growth of new tissue in that place. Then, too, in certain cases of catarrh where the condition is very marked, there is also at the same time a diminution in the secretion from several causes, and there is like to be in cases of chronic catarrh a great deal of interstitial inflammation, that is to say, connective tissue formation between the groups of tubules so that many of them are squeezed and distorted and have not the power to produce the proper secretion—a condition analogous to that which occurs in interstitial disease of the kidney.

So far as danger is concerned, I have never seen any at all from the passage of the stomach-tube. Recently hæmorrhage is regarded as a contraindication for the use of any such local means as this, chiefly for the reason that rest of course is the thing always desirable in the case of a recent ulceration or one which is deeper.

As far as the hydrostatic pressure is concerned, the only thing to do is to let the water run in, and if you hold the tube just above the level of the stomach, as is usually done, it runs in very readily and there is no more lateral expansive force than there is from the secretion which is already there. It is ordinarily the custom to pass the tube down into the stomach and pour in the water from a height so that it will just run in and no more, and there is no danger of getting too much pressure if you do not get too much water. If you fill the patient up too full, he simply nods his head and regurgitates and up it comes. I do not think it is a wise thing to see how much fluid one can get into the stomach; it is useless. If there is evidence that the stomach is not able to pass on the food as it should, it is of no sort of use whether you can get in one quart of water or a dozen. You simply want to wash the stomach clean, and having done that, that is all you care for.

As far as the distension of the stomach with air is concerned, the best way is to follow out the method which has been used in some of the foreign clinics for a number of years; that is, to blow up with air by means of a Davidson syringe through the tube. In that way you put in at each squeezing of the bulb, the bulk of two ounces of air and can control it instantly. If the patient suffers pain, you simply withdraw the nozzle of the syringe and let some air out, so that it is not under pressure. It is found that a relatively small amount of air is necessary to start up the process of contraction and bring the folds of the stomach in relief so that you can see them. You can pump in a considerable amount, but that is not a wise thing any more than you would wish to over-distend a man's bladder with water to see how much it will possibly contain. There

is no likelihood for this to happen except in demonstration before classes of students where sometimes inadvertently one might get in more than one desires.

As far as the etiology of the diseased condition is concerned, that is manifold. There are quite a number of different conditions which bring it about, but it was not within the province of this paper to speak of them. It was only the condition of dilatation after it existed that I wished to discuss. It does not make any difference whether the dilatation is the result of cicatricial stenosis or cancerous stenosis or pressure of tumor outside or what not, the treatment at first is the same, and the conditions which enable you to make out the diagnosis is the same. You can make the patient comfortable; you can fix him so that he can do his work; and you can make his life endurable. It was not so before, and he was removed from a great many of the pleasures of life which this simple method of procedure—and it always seemed to me a harmless one—will give him.

DR. E. H. BRADFORD reported a case of

#### ANEURISM OF THE EXTERNAL ILIAC ARTERY.<sup>2</sup>

DR. G. W. GAY: Those who have had much to do with aneurisms will agree with me when I say the diagnosis is not always easy to make out. I have made my share of mistakes in this department as I suppose every surgeon has who has had much to do with a large number of persons in the hospital. It was once my ill fortune to explore a trouble in the anterior mediastinum, which some of our best clinicians thought was not an aneurism. The exploring needle was first used, and the evidence not being conclusive a small incision was made just above the clavicle, and that on being dilated proved that it was an aneurism. The exploration was made after several paroxysms of dyspnoea which seemed to threaten his life, and it was a question whether it was an abscess there or something else. It proved to be an aneurism without any of the ordinary signs or symptoms of aneurism.

Again, a man came under my care with a large tumor in the axilla. The arm had been amputated several years before for a gunshot wound. There was no pulsation whatever. It was a lobulated tumor, elastic, painless, and had been in existence about two years. It was thought to be sarcoma. An incision into it gave exit to a little brownish, coffee-colored fluid. On exploring the interior of this sac a little more thoroughly, a stringy mass of lymph was found at the bottom. On examining that a little more carefully red blood came, and the diagnosis was made. The subclavian artery was tied and the man got well, and is well to-day. With the arm missing, I do not see how it would have been possible to determine the diagnosis in that case without an exploratory incision.

I once saw one of the best surgeons this city has ever produced amputate a thigh for an aneurism of the popliteal space, which was only discovered after the operation. There were absolutely no symptoms pointing to that disease.

A darky once came to the hospital with a swelling of the popliteal space, which was precisely like that which was described, and which existed in Dr. Bradford's patient, a large, hard, brawny, non-pulsating tumor which had been there for a long time. Whether the vessels pulsed below I do not remember. That tumor was aspirated and found to contain blood. Noth-

<sup>2</sup> See page 593 of the Journal.

ing more was done for two weeks, when pulsation appeared, owing to the patient being put to bed, kept quiet, his limb elevated and the congestion and diffusion around the aneurism being allowed to subside. Then the diagnosis was clear. The femoral was tied, the patient got well, went out, and returned after three months with gangrene of half of the leg to the knee. The leg was amputated, and the man got well.

All these cases show that the diagnosis of aneurism is not so simple as we have been led to suppose.

DR. F. B. HARRINGTON: I would like to ask Dr. Bradford whether in a case similar to his, with the knowledge that he was dealing with an aneurism, it would not be justifiable to make an effort to tie the common iliac, not knowing the obstacles you are going to meet.

DR. BRADFORD: It would anatomically have been feasible I think, but clinically the possibility in this individual case seems questionable.

DR. HARRINGTON: Whether one ought to leave such a case without making an attempt, not knowing how short a space one had to tie, is the point I wish to settle in my mind.

DR. GAY: I think one important point in these cases is the pulsation of the arteries below. I do not know what the condition of the arteries was in Dr. Bradford's case. I think in one of my cases that fact was overlooked, and that fact is forcibly brought to mind by a case I recently saw. A man was kicked in the leg, his leg hitting against a spike striking over the femoral artery. The story given to me was that the man had fainted away after the kick, had several attacks of sharp acute pain sufficient to make him faint and had a distinct enlargement after each attack. I thought that the femoral was ruptured, and that the reappearance of the hemorrhage accounted for the pain. The only thing against that was the fact that the arteries below this bunch were intact. The anterior and posterior tibial could be felt distinctly. The tumor was opened, the blood turned out and it was found to be simply rupture of the small vessels not the large ones. If I had found the arteries below were not pulsating I should have expected to find rupture of the femoral artery. I think that is an important point in the diagnosis of these cases.

DR. M. H. RICHARDSON: I think the subject is very important, and I am very glad to hear Dr. Bradford's paper and Dr. Gay's remarks on the subject. I never have been so placed, but dare say I shall be. I have had a very slight experience with aneurism. I have been in the habit of exploring tumors in regions which are commonly the seat of aneurism with a very fine needle even in the absence of any signs of aneurismal dilatation, but I think even in the preliminary exploration that we cannot be sure that an aneurism is not present. I think that the case is very valuable, and I think we are indebted to Dr. Bradford for bringing it out. We certainly learn very much more by such cases than we do by successful ones.

DR. HARRINGTON: I should like to ask Dr. Bradford, given the knowledge he has, what he would do in a similar case.

DR. BRADFORD: I certainly should not have operated, it it was one of those where a more thorough examination would have perhaps made the diagnosis more clear and would have contraindicated the operation.

DR. GAY: One other case that resembles somewhat

Dr. Bradford's. Dr. Edson asked me to see a woman suffering from septicæmia, who had a tumor in the pelvis of some weeks' duration. The patient was in an extreme condition of blood-poisoning. The aspirator gave exit to some bloody, stinking matter, which we supposed came from an abscess. She was etherized. This bunch was opened and found to be a suppurating hæmatocele. The external iliac was leaking and the abscess was packed with iodoform gauze. She was immediately removed to the hospital, re-etherized, the packing removed, everything cleared out, a large incision made running up above the tumor to give control of the common iliac artery if possible. On getting into the peritoneal cavity and down on the abdominal vessel it was found that the effusion extended so high that the abdominal aorta was the only possible way to get at vessels above the tumor and stop the bleeding. Then our attention was attracted to the interior of the sac, that having been thoroughly cleared out the bleeding point was readily seen, but it could not be secured. The vessel was so thoroughly surrounded and matted into this inflammatory material it was impossible to dissect it out. The forceps was applied, the abscess packed and the patient made as comfortable as possible. She died in the course of two days. I fully sympathize with Dr. Bradford that this is one of the most difficult positions a surgeon can find himself in, but he has the consolation of knowing that he is not the only one who has been in these places.

DR. BRADFORD: The ease with which the bifurcation of the aorta can be reached by stripping up the peritoneum was quite noticeable in this case.

Dr. Bradford also reported a case of

#### BULLET-WOUND OF THE SKULL.\*

He had been quite interested in wondering how the bullet could have acted as it did. The butt end lay on the dura, and of course it is not possible that the bullet was in the cartridge with the butt end foremost, and it was evidently flattened out at the point of impact, that is, at the point. It is evident, though it hardly seems credible, that it could have turned so completely from the point of impact to the point in which it lay.

DR. BURRELL: It has not been my fortune to see a bullet revolve in that fashion in the skull, but I have seen that sequence of events where a bullet was fired through two boards, first through one board and impacted on the second board, here there was a direct revolution of the bullet. In the bullet-firing that I have seen, I have come to the conclusion that no one can tell where a bullet is going to bring up. It is received on a plane surface of board, and may glance in any direction, may revolve on its own axis, as in Dr. Bradford's case, or pursue a straight course.

#### TREPAPHING FOR EPILEPSY,

by DR. E. H. BRADFORD.

Two cases of trephining for epilepsy were mentioned, and the trephine buttons were shown. In both these instances there had been a history of a fall and an injury to the head sometime before the epileptic symptoms. The exact site of the injury was not known. In one case the patient was of adult age; in the other a child of six. In the second instance the child was somewhat deficient mentally. In one instance the pain attending it was referred to a certain portion of the skull. On palpation a slight depression was

\* See page 513 of the Journal.

felt. In the other instance, the depression was felt, but there was no pain in that region. The depression could be readily recognized on careful palpation, and was sufficiently well marked to attract a degree of attention of the surgeon searching for injury following a fall. In both these instances trephining was done with some amelioration of the patient's symptoms. But although the depression was felt before the operation, and to be seen to a marked degree on the outer table of the trephine button, on the inner table there was no evidence whatever of any depression; demonstrating that there may be a depression of the skull noticeable on palpation externally, without a corresponding depression internally, and with no evidence in the bone of the existence of any previous injury to the bone, in other words, the specimens indicate non-traumatic dents in the outer table of the skull.

DR. M. H. RICHARDSON showed two specimens of

#### GALL-STONES REMOVED FROM THE CYSTIC DUCT.

The first specimen is a very small stone. The diagnosis was made by Drs. F. C. Shattuck and Cutler, and an operation for relief was advised. The gall-stone was impacted where these gentlemen said it was, in the cystic duct, and this stone was situated in the cystic duct of a very much contracted gall-bladder. This is the third operation on the gall-bladder I have had for gall-stones, and this illustrated the great contraction and thickening of the wall and its friable condition. If any of you have to operate on the gall-bladder, and have not had experience, you will find the gall-bladder so friable as to interfere with the success of the operation and jeopardize the patient's life.

The next case was a gentleman of sixty-four, who had been troubled eight years with biliary colic, and his life had been miserable that time. He has been abroad every year to get relief from the medicinal properties of the waters of the chief springs. He came home from Carlsbad the other day, and has required morphine injections to make him comfortable. He decided to have an operation done. In this case we found eight large gall-stones in a row in the cystic duct, and extending out into the contracted gall-bladder with its thickened, friable and bleeding walls. All that was necessary was to open the gall-bladder and remove these stones.

Both these cases have done remarkably well. The boy now, at the end of a week, is in very good condition. The second case was done Saturday morning, and the temperature is normal.

I would like to mention a case I had a year ago. A woman who had suffered many years with symptoms of biliary colic, marked jaundice and profound choleraemia: I opened the gall bladder and found it contracted, and in that case I was confronted after the removal of the stones with a formidable condition of vast quantities of bile escaping down by the foramen of Winslow.

I have two specimens of vermiform appendix in both of which cases I removed the appendix. I treated all the cases in the same way, that is, in the question of sepsis or where septic fluid had escaped into the abdominal cavity, I packed them all deeply with gauze, and in all the cases the results were most gratifying. This is nothing new, but I never had so much experience in packing deep the abdominal cavity with gauze, separating the intestines for forty-eight hours,

and forming a perfectly safe exit for any septic fluid which has been forming.

In the cases of operation upon the gall-bladder, the gall-bladder had thick walls, and was very friable indeed. In this case the gall-bladder tore all to pieces, and we had the cystic duct open and the common duct, and enormous quantities of bile coming out way down in the liver. In that case I simply put a glass tube in here, placed it in position, and packed all around on both sides with gauze. I don't think it would make any difference with iodoform or any kind of gauze. A fistula immediately formed. The woman did well for six or seven weeks, although there was no diminution of the amount of bile or jaundice. At the end of that time she had septic temperature, and died from the results of a sponge which was left in at the time of the operation in spite of the usual precautions to prevent, namely, counting all the sponges before and after the operation.

In the case of the boy I tried to sew the gall-bladder to the abdominal parietes. The thing tore all to pieces in spite of all the care I could use, and finally I had no recourse except to put in a glass tube and tie around here. That did not work, so that finally I had nothing to do except to tie this gall-bladder entirely off, and pack all around with gauze, but the gall-stones which had been so impacted there, produced such a thinning of the wall that after ligation was applied, the bile escaped with great profusion, and that was provided for by the sponge and the gauze. It pleased me very much indeed that the gauze should have acted in that way.

DR. FITZ: In these operations of Dr. Richardson, I would like to ask whether he considered the expediency of tying the cystic duct and removing the gall-bladder.

DR. RICHARDSON: In this case that was done.

DR. FITZ: Still leakage took place in the case of the young man. In the other case where a fistula was made into the gall-bladder, whether such an operation commends itself to the surgeon?

DR. RICHARDSON: Yes, if the gall-bladder is contracted so that you cannot make a fistula easily.

DR. FITZ: In these cases of biliary calculi it is not so much perhaps the presence of calculi in the gall-bladder at any time, but the tendency of the individual to form calculi.

DR. RICHARDSON: I think the difficulty is in closing the gall-bladder or in closing the duct. I think you are apt to get a fistula unless you sew something over the duct to close it.

DR. FITZ: I have the impression that Sir Spencer Wells considered in these operations for gall-stones the thing to aim at was the removal of the gall-bladder and attempt to close the cystic duct. I do not know whether that in practice resulted favorably.

DR. RICHARDSON: It seems to me a more difficult and dangerous operation. If gall-stones form again, nothing is easier than to get them out. All you have to do is to make an incision through the other cut.

DR. FITZ: I suppose surgeons have the hope of closing the fistula later?

DR. RICHARDSON: The fistula closes, takes care of itself.

DR. FITZ showed a specimen of

#### ANEURISM OF THE AORTA.

interesting from the extent of the disease, the com-

parative freedom from inconvenience and the absence of characteristic symptoms of an aneurism. It came from a man who walked into the hospital a few days ago, suffering from a certain amount of annoyance in swallowing, especially when large mouthfuls were taken. He was not obliged to abstain from solid food. This was the only symptom of which he complained; and he appeared for a man of his years, sixty-two, in excellent condition. The difficulty in swallowing led to the suggestion of an ulcer of, or pressure upon, the œsophagus. On physical examination, there was nothing abnormal found in the circulatory apparatus. The pulsations in both radials and temporals were normal, and the arteries were not rigid. The position and sounds of the heart were normal. The resonance in both chests was also normal, perhaps a little hyper-resonant. At the base of the sternum, however, there was a circumscribed dulness extending nearly to the notch, its borders defined by the edges of the sternum. No pulsations to be observed, and on palpation nothing like a thrill. No abnormal signs on auscultation of the heart or lungs nor was there any interference with respiration. With these conditions there was also a very slight degree of hoarseness, hardly sufficient to attract attention, yet, in connection with a certain amount of discomfort in swallowing, an important sign. Dr. Hooper examined the larynx and reported a paralysis of the left vocal cord. The clinical picture suggested a tumor which was interfering with the function of the left recurrent laryngeal and which also was pressing to slight degree on the œsophagus. Aneurism of the a-ascending portion of the arch was the most satisfactory explanation, and yet he had no severe symptoms. He walked about, ate food without especial difficulty, had no disturbance of respiration or circulation, and, during three or four days at the hospital, expressed himself as comfortable. He went out daily, and, while sitting under a tree, suddenly a gush of blood took place from the nostrils. The immediate cause of death proved to be the rupture of an aneurism into the left primary bronchus. The specimen illustrates the fact of their being no sharply-defined tumor, but a more or less uniform dilatation of the arch and of the entire thoracic aorta, also just above the diaphragm, a larger circumscribed dilatation, the wall of which was formed by two eroded dorsal vertebrae. This erosion had taken place without pain. The rupture is a little sac projecting from the generally dilated surface of the aorta. It was filled with a thrombus, but the tissues beneath that and the bronchial cavity had suddenly given way.

#### AMERICAN GYNECOLOGICAL SOCIETY.

SIXTEENTH ANNUAL MEETING HELD AT WASHINGTON, SEPTEMBER 22-23, 1891.

(Continued from No. 22, page 577.)

DR. A. RILEY JACKSON, President, of Chicago, presented the

#### ANNUAL ADDRESS.

He reviewed the work of the Society in the past, and referred with much feeling to the recent death of Dr. Fordey Barker, one of its founders and its first presiding officer. He had occasion also to mourn the death of Dr. David Humphrey Storer, of Boston, an

honorary member, and Dr. George H. Lyman, one of the founders.

Reviewing the field of gynecology during the fifteen years since the Society was founded, he pointed out the manner in which the advocates of this or that operative procedure had become extremists. The total extirpation of the uterine appendages was a most striking instance of this tendency. He considered it a crime when simpler treatment could be adopted. He protested against the too frequent examinations of the pelvic organs of young girls and unmarried women, and condemned the practice of publishing hasty and immature reports of surgical work, which had not undergone the test of time.

#### DR. WM. H. BAKER, of Boston, read a paper entitled, CANCER OF THE CERVIX UTERI—RESULTS IN ITS TREATMENT BY HIGH AMPUTATION.

The writer referred to the great importance of tracing the future history of these cases. After much labor, he was able to report the complete histories of the first series of ten cases reported in 1882. The specialist sees comparatively few cases sufficiently early to accomplish much by a radical operation because the early symptoms are not marked, and the hemorrhage and leucorrhœa are supposed by the patient to be incident to the menopause, and also because the physician fails to recognize in many cases the importance of the condition, or else, if he does recognize the diseased condition, lacks faith in the possibility of its removal. Of the ten cases reported in 1882 as having been operated on without a death, eight were then living and well. In 1886, six of these were then living and well, or about sixty per cent. after a period of from four to eight years. At the present time, fifty per cent. of the original cases are living and well after a period of from ten to twelve years.

In a second series of cases, from 1882 to 1889, there was no recurrence of the disease in 62½ per cent. of the cases operated upon.

The writer emphasized the great necessity of thoroughly cauterizing the raw surfaces after the removal of the growth by the knife. He claims for the high amputation, as compared with hysterectomy, greater safety to the life of the patient, and longer respite from any recurrence of the disease.

His conclusions were: (1) That a thorough removal of all the disease should first be made with the scissors or scalpel, keeping well outside the infiltration, and apparently in healthy tissue. (2) That the wound should not be immediately closed, but that every portion of it should be kept under observation until entirely healed. (3) That the thorough application of the cautery is an all important factor in the success of the operation. (4) That it is often necessary to do some slight secondary operation to insure success. (5) That the cases must be under close observation for years.

In all cases of cancer of the cervix, which have not become fixed by an extension of the disease, high amputation with the application of the cautery immediately following, is the safest and best method of treatment. Vaginal hysterectomy should be reserved for cases of cancer primarily affecting the corpus uteri, or where the disease has extended to the corpus uteri without fixing the uterus.

DR. JOHN BYRKE, of Brooklyn, believed that high amputation could be as completely done with a delicate

galvano-cantery knife as with the scalpel or the scissors.

DR. HENRY J. GARRIGUES, of New York, read a paper on

#### THE BEST POSTURE IN THE DIFFERENT STAGES OF NORMAL LABOR.

A change has taken place in the customary position in which women are delivered in the United States. Now some speak of an American (dorsal) position as opposed to the English (left lateral), while until thirty years ago nearly all American obstetric authors recommended the English position.

In deciding the posture a woman should occupy during labor, we must take into consideration her comfort and safety, the child's safety, and the accoucheur's comfort, which again contributes to the mother's safety. While the child is passing through the bony part of the parturient canal the semi-recumbent position on the back is best. The contraction of voluntary muscles and gravity co-operate with the contraction of the womb; the entrance of the head into the superior strait is favored; the stethoscope can easily be applied to the abdomen; manual pressure may be exercised on the womb. Sometimes a change of position is useful.

When the vulva begins to open, the patient should be turned on the left side, and lie horizontally, her thighs at right angles with the trunk, and the legs and the lumbar region stretched. All support should be taken away from hands and feet, and chloroform should be given. In this position the os coccygis has free scope to recede backward; the genitals become visible and easily accessible, while the rest of the body remains covered, whereby exposure to cold is avoided; the patient does not see the accoucheur and has a feeling of being hidden. Abdominal pressure is limited; the fundus sinks down, so that gravitation works in a direction opposite to that of uterine contraction. The left lateral position affords a safe-guard to the perineum and prevents the head from emerging too suddenly. During and after the expulsion of the placenta, the woman should be on her back, with the head low, a position better adapted to Crede's method than the English.

The kneeling, squatting posture is fatiguing, predisposes to fainting and hemorrhage, makes the use of the stethoscope difficult, nearly excludes any kind of protection of the perineum, and renders the use of chloroform impossible, though in cases of lingering labor it may be tried.

DR. W. GILL WYLIE read a paper on the

#### INFLUENCE OF IMPERFECT DEVELOPMENT AS A CAUSE OF UTERINE DISEASE.

The most important influence at work in causing uterine disease is the tendency to restrict the physical development of our females just at the time when they are changing from girls to women. The generative organs are practically dormant until about the tenth year, when they begin to develop and make a large demand on the system up to about the sixteenth year. To ensure full development during this period a girl must have a surplus of physical and nerve force. If the girl is pushed at school, or her force is used up by constant contact with older intellectual people during this period of development, she is almost certain to have a leucorrhœal discharge and dysmenorrhœa, and an imperfectly developed uterus, with disease of the

glands and follicles, which predisposes her to catarrhal endometritis, the development of new growths, such as cancer or fibromata, and if marriage and pregnancy follow the labor is apt to result in laceration of the cervix, or if unmarried the catarrhal condition is pretty certain to result in sterility.

As preventatives of this condition of imperfect development the author recommended that during the period of active development the general health should be maintained, the bowels kept regular, and healthful play out of doors, and pleasing mental occupation should take the place of an in-door life, forced cramming, and stimulating contact with older people.

The imperfect development of the generative organs with their attendant conditions should not be lost sight of in treating the various diseases to which women are subject.

DR. A. W. JOHNSTONE, of Cincinnati, believed that if there were no infantile uteri there would be no lacerated cervixes, and that quite a large per cent. of cystic ovaries and diseased tubes were due to an infantile body.

DR. HORACE T. HANKS, of New York, read a paper entitled,

#### SUGGESTIONS OF CERTAIN RULES TO BE FOLLOWED IN THE EFFORT TO PREVENT MURAL ABSCESES, ABDOMINAL SINUSES, AND VENTRAL HERNIA, AFTER LAPAROTOMY.

Abscesses in the line of the abdominal incision after laparotomy tend to make a track for a later ventral hernia. In trying to avoid mural abscess we should make a clean-cut wound, separating the different layers carefully; do not retract the lips with too much force or too long pressure; do not use too hot water or too strong a germicide on the lips; have the abdomen aseptic by means of a germicide dressing some hours before the operation. Do an aseptic operation. Remove the dressing every second day. Before cutting the sutures have the patient wear a moist bichloride dressing two or more hours, and be sure no sepsis in any way whatever is taken into the wound when the sutures are withdrawn. Make no unnecessary punctures with needles; do not strangulate the wound with too tight tying of the deep sutures.

To avoid sinuses: Never use a drainage-tube when not necessary; never allow a tube to remain *in situ* more than twenty hours; keep the tube sweet and clean.

Ventral hernia is much more frequent than is generally supposed. The author believed it could be prevented by a more careful apposition of the different layers of peritoneum muscles and fascia, taking care not to strangulate the deeper tissues by suturing too tightly. He used silk worm gut sutures.

DR. EMER believed the silver-wire suture should be used in preference to all others because it enabled a more perfect coaptation of the edges of the wound. If the silk suture was used it was likely to have the effect of doubling the abdominal wall on itself, and producing a union between the peritoneum and the skin, which he believed was a frequent cause of hernia in these cases.

DR. BYFORD believed two important causes to be sepsis and dead material in the wound. In operating for half an hour there is apt to be a certain amount of lacerating of the fatty tissue around the edges of the wound, and in order to get perfect union a certain

amount of this wounded fat must be cut away, otherwise it is dead tissue. The worst abscesses he had met with were in cases where he had used buried sutures. He preferred the silk-worm-gut suture, introducing it with a curved needle, the suture describing a circle and preventing the peritoneum from pushing up into the wound.

DR. W. GILL WYLIE recognized the fact that below the umbilicus the peritoneum is a loose tissue with little strength, which must be cleanly cut without tearing it. The recti muscles are longitudinal muscles, and their transverse strength, excluding their fascial covering, amounts to little. In opening the abdomen, he would avoid that point and open in the linea alba. It was of vital importance to get perfect union of the deep fascia.

DR. ANDREW F. CURRIER, of New York, read a paper entitled,

A STUDY RELATIVE TO THE FUNCTIONS OF THE REPRODUCTIVE APPARATUS IN AMERICAN AND INDIAN WOMEN.

The facts contained in the paper were obtained through the Indian Bureau, to the officers of which the author acknowledged his obligation. Among most tribes puberty was reached at an average age of about fifteen years. Savage life *per se*, neither hastens nor retards puberty, but climate, occupation, and hereditary tendency are the important factors. The hardships of savage life do not usually interfere with the regular recurrence of menstruation. Excessive menstruation is practically unknown. There are, however, occasional instances of dysmenorrhea or amenorrhea in connection with disease or deformity of the pelvic organs. The nervous and vascular disturbances which so commonly accompany the menopause in civilized women are notably absent. The duration of the menopause varies as greatly as it does in civilized life; the exposure and physical suffering incidental to a savage life does not tend to shorten the menstrual and child-bearing periods. Marriage is mainly a matter of convenience or inclination with nothing especially binding about it. It is consummated in many cases almost as soon as puberty is reached. Conception and gestation are favored by an ardent sexual appetite and out-of-door life. Abortion seldom occurs as the result of severe labor, but is common enough as the result of syphilis and criminal interference, the latter of which is fearfully prevalent.

Parturition is usually a natural and easy process, it having been described as being about as easy as for a cow to have a calf. The favorite position during labor is the kneeling one, the arms, chest and head resting upon a support of some kind. The accidents of parturition are few, occurring perhaps as frequently as in the lower animals. Puerperal disease is almost unknown; malignant disease of the generative organs is likewise seldom met with. Both local and constitutional forms of venereal disease abound. The frequency of syphilis coupled with the great mortality among infants, and the great prevalence of glandular and pulmonary disease among many of those who survive infancy, are evidences of the inroads which venereal disease has made upon Indian vitality.

Conclusions: Indian women in the savage state undergo less physical suffering in connection with the reproductive apparatus than do civilized women for three reasons: (1) natural or racial insensitiveness,

compared with the far more sensitive Caucasian; (2) abundance of exercise; (3) life in the open air.

Civilized life with its complex conditions will always present obstacles to the performance of the functions peculiar to women with the same ease with which they are experienced by savages; and when Indian women exchange the savage for the civilized state, it is found they also become subject to some of the ills which are inseparable from the latter.

PROF. F. WINCKEL, of Munich, presented a paper (read by Dr. J. C. Reeve) entitled,

THE TREATMENT OF EXTRA-UTERINE PREGNANCY.

Most publications of the present day upon the treatment of extra-uterine pregnancy are either on the electrical destruction of the fœtus, or laparotomy for the removal of the amniotic sac and its contents.

The method of injecting morphine into the amniotic sac, which the writer has taught for over a decade, has been lost sight of in the overstrained estimate of laparotomy, which continues to be the favorite method. He, however, believes it to be good practice in many cases, and has recently cured two cases, destroying the fœtus in each, the patients recovering.

There is no question that the inflammation of the pelvic organs preceding extra-uterine pregnancy may naturally enough continue after the death of the fœtus, and may be the cause of many complaints, but that the presence of the dead fœtus is the cause of these symptoms cannot be regarded as proven.

The writer related a case of a ten months' tubal pregnancy, where laparotomy was performed, child and placenta extracted, tubal sac mopped out with iodoform gauze and sewed up. Patient perfectly well when discharged, and shortly afterward menstruation appeared. This was undoubtedly a case where laparotomy was the only rational treatment. The necessity of laparotomy in certain cases of extra-uterine pregnancy was proven by the writer twenty-seven years ago, when he did his first laparotomy; but his experience has taught him that it is not necessary to operate in the first few months of extra-uterine pregnancy, but to treat such cases by injection of morphine into the amniotic sac, which is easier and better. The woman is not mutilated, she has both ovaries and tubes remaining, and even the possibility of the tube which formerly was impregnated, after resorption, again performing its functions. If, after the death of the fœtus by morphine, the patient complains of great physical suffering, then a laparotomy is still possible, and the operation even then is less dangerous.

The injection of morphine into the amniotic sac can be made by any practising physician; the extirpation of the sac by laparotomy cannot be successfully made except by a skilled operator.

(To be continued.)

DETERMINATION OF SUGAR IN DIABETIC URINE BY THE MUSCIMETRIC METHOD.—The following is from the *American Druggist*:—Prepare a one per cent. solution of grape sugar in healthy urine, pour it on a soup plate; on another plate pour an equal volume of the diabetic urine; evaporate both to a syrupy consistency, then expose both plates in a place where there are flies. After ten or fifteen minutes count the flies on each plate, divide the number on the diabetic urine by the number on the grape sugar solution, which will give the percentage.

THE BOSTON

## Medical and Surgical Journal.

THURSDAY, DECEMBER 3, 1891.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANIELL & UPHAM,

## NEW RESEARCHES ON VARIOLA VACCINE.

UNDER the above title an editorial article appeared in this JOURNAL, January 22, 1891. Some interesting experiments by Hæcius and Eternod, of Geneva, were there recorded, the ultimatum of which was that the identity of small-pox and the vaccine disease was rendered more than probable. Chauveau, Chief of the Lyonesse Commission, which, in 1865, announced as the result of careful studies and experimentation conclusions since then generally accepted by the profession, has reviewed the communication of Hæcius and his colleague, having repeated with some of their lymph their experiments. The lymph was the product of the eighth transmission from heifer to heifer, and was furnished directly to Chauveau by the Genevan professors. Chauveau's trials were made exclusively on subjects of the bovine species. The primary eruption which follows the inoculation constantly maintains special characters which differentiate it from the vaccinal eruption. At the same time, this special eruption is the result of an infection which has close relations with vaccine, for it is no longer possible to vaccinate animals thus variolized. M. Chauveau finds no evidence of that transformation of small-pox into the vaccine disease which the Genevan professors claim to have effected by passing their lymph through a succession of cattle, the original virus being variolic. The very full account which he gives of his experiments seems to prove his contention that the lymph which he received from Eternod and Hæcius was variolic lymph and not vaccine, always producing, when inoculated in healthy cows, a typical variolic eruption. It was a repetition of experiments which, as one of the members of the famous Lyon's Commission, he had performed nearly forty years ago.

Without taking up space by presenting a more lengthy summary of M. Chauveau's paper, which is printed in full in the Reports of the Academy of Medicine and in other French journals, we will state his conclusions: (1) Vaccine virus never gives small-pox

to man. (2) Variolic virus never gives vaccine to the cow or horse. (3) Vaccine is not even attenuated small-pox, and cannot be compared to the benign anthracoid infection which is communicated to animals by inoculation with attenuated anthracoid virus. (4) If vaccine is a derivative of small-pox it is by reason of a radical transformation of the variolic virus, a transformation thus far unattainable by experimenters. (5) These last propositions lead to another more general proposition, which is this: the attenuation of virus is not a physical process which can be identified with the transformation of virus.

This being granted, how, it may be asked, does vaccine virus confer immunity from small-pox?

If we do not know exactly the mechanism of this immunity, the essential cause on which it depends is well known. On reviewing all the systems of preventive inoculation, we come upon three methods which may be treated under the following heads:

(a) Fabrication of prophylactic substances by pathogenic agents outside of the organism to be rendered immune, and the introduction into this organism of the said substances in sufficient quantity to confer immunity, these substances having been, by the proper manipulations, freed from the virulent elements properly so called, and rendered inoffensive.

(b) Fabrication in the organism to be protected of prophylactic substances by the pathogenic agents, with the germs of which inoculation has been made under conditions which ensure the benignity of their infectious effects.

(c) Fabrication of the vaccinal substance by a virus very like the virus against which immunity is sought, but belonging to another species.

In this latter category, Chauveau places the microbe of chicken cholera in its function of conferring immunity against charbon. Here, also, he would put the virus employed as a preservative from small-pox. Whatever, in fact, may be the origin of vaccine, though we were to admit it to be a derivative of small-pox, it none the less constitutes in reality a morbid species distinct from the latter. The two viruses, vaccinal and variolic, are irreducible into one and the same infectious entity.

It is probable that for some time to come the above will be "the last word" on the subject. Satisfactory experiments of this kind are difficult of performance, for no experimentation on animals can be regarded as complete whose results have not been checked by inoculations practised on the human subject. Now, Hæcius and Eternod did not try their lymph—rendered vaccinal, as they believed, by several removes—on the unvaccinated child, nor did Chauveau make any such trials. Of course, there is an obvious reason why such experiments cannot well be attempted, and it would be nothing less than criminal to inoculate a human being with a virus which might possibly be variolic and a means of death.

The human race has not yet reached that stage of perfection described by Bulwer in his posthumous

novel; when, in his underground Utopia, it was considered lawful to sacrifice almost any number of human beings in the interest of science.

Nevertheless, if we may not for many years to come know more about the relations which exist between vaccine and variola, enough data have been obtained to establish the fact that vaccine does protect, and we are daily learning more about the vexed question of immunity.

#### THE DUTY OF PHYSICIANS TO REPORT CASES OF TYPHOID FEVER.

It is well known that many physicians neglect altogether to report to Boards of Health those cases of typhoid fever which come under their care. This neglect is defended by some upon the ground that such reporting can do no good; by others, because their patients dislike to be "reported," and because if they are reported they will henceforward refuse to employ them. Unquestionably it is unpleasant for a household to be "reported" to an official body and to become an object of investigation. Doubtless the visits of the inspectors, who may sometimes be of a political, rather than a scientific, character; their prying into the plumbing, and their apparently irrelevant and even impudent questions about milkman and drinking-water, do appear to the household afflicted with typhoid fever as at least an interference, and sometimes as irreverent when, for example, the household regards the disease as an inscrutable affliction of divine Providence.

And yet, neither of these reasons for the neglect can justify it. If it is the duty of the attending physician to report any specific disease, it is as much his duty to report his cases of typhoid fever as it is those of small-pox or scarlet fever.

The Lowell Board of Health, which enjoys an excellent reputation among the boards of Massachusetts, having long suffered, as most boards of health do suffer, from the neglect of physicians in regard to reporting typhoid fever cases, has at length taken a decided stand, which is worthy of commendation, and have issued the following circular to the physicians of that city:

GENTLEMEN:—The City of Lowell has for many years suffered severely from typhoid fever, and to such an extent in the later months of 1890, that the best expert assistance was called to make a thorough and exhaustive investigation, which was done at a considerable expense.

In 1888 there were 63 deaths from typhoid fever; in 1889, 65 deaths; in 1890, 173 deaths; in 1891 to November 1, 63 deaths. Cases reported in 1890, 171; in 1891 to November 1, 238.

The Lowell Board of Health, in April, 1888, under the authority of the Public Statutes, chapter 80, section 18,—"The Board shall make such regulations as it judges necessary for the public health and safety. Whoever violates any such regulation shall forfeit a sum not exceeding one hundred dollars,"—included typhoid fever in the list of diseases considered dangerous to the public health, and required physicians to report them to the Board.

Rule 2. The Board consider that varioloid, membranous croup, measles and typhoid fever are diseases dangerous to the public health, and require immediate notification of their occurrence.

They have been aware, since then, that typhoid fever has not been reported by physicians with the same promptness and reg-

ularity as are the more contagious diseases, diphtheria and scarlet fever.

In the report of 1888 it was remarked, "Physicians who have not given the matter thought often ask what benefit is derived from reporting typhoid fever to the Board of Health, since there is no need of isolation or fumigation." While typhoid fever is most frequently introduced into the system by contamination of drinking-water with its germs, it may be introduced by direct contact with the patient and his discharges. Circulars relative to typhoid fever are sent to every householder where a case exists; disinfection of the dejecta, advised in this circular, may save the occurrence of a second case of the disease. An inspection of the premises may discover the source of the disease, or prevent the contamination of the water supply of other families.

The fact that there frequently are unsanitary surroundings in typhoid fever which can be remedied is a strong reason why this disease should be reported to the Board of Health. The Board is aware that the percentage of deaths to reported cases is very much larger than it should be, and appearing in the reports of the Board, is examined and criticised as reliable statistics, when it is very incorrect and misleading. Even if nothing were gained by reporting the disease, other than an opportunity to make a scientific investigation as to the causes of the malady, then it should be reported.

It seems as if some physicians were interested in disease wholly from a financial point of view, and the neglect we complain of is constantly growing worse instead of better. The physician who reports typhoid fever at present is the exception, and not the rule.

There were seven deaths in October, 1891, from typhoid fever, and but one reported to the Board of Health either before or after death.

As these deaths were not reported to the Board, notwithstanding the oft-repeated requests that the disease should be reported, they are strongly and unanimously of the opinion that more stringent measures are absolutely necessary, and they have, therefore, voted the following resolution:

"On and after December, 1891, upon the presentation of a death certificate at the office of the Board of Health, the person having died of typhoid fever, in the absence of a previous report of the disease by the attending physician, a warrant will be asked, and if granted, a prosecution will be commenced by the Board in each and every case."

It must not be supposed that the physicians in Lowell are sinners above all the physicians of Massachusetts. The fact probably is, that they fairly represent, in this respect, the profession throughout all of the cities of the State. But as we have already intimated, this neglect is not only indefensible, but it is also discreditable to the profession, and the Lowell Board of Health is to be warmly commended for what it has done.

The medical profession makes many gratuitous sacrifices of time, skill and trouble for the public good—many sacrifices which often are not recognized and not appreciated by the public for whose good they are made. As a rule, these sacrifices are made cheerfully. To them should, and must be added the diligent reporting of required diseases to the local boards of health. It is emphatically the duty of our profession to set an example of obedience to sanitary authorities.

#### CUTTING AND SUBSTITUTING.

The American public is proverbially addicted to the habit of dosing itself. Whether this fact is the cause or the effect of the vast quantity of proprietary medicines with which the country is flooded we shall not discuss, but the result is everywhere felt by the apothecary; he must keep a supply of what is demanded of

him by his customers. This in itself is bad enough, but in addition he finds that many of the favorite nostrums are sold at cut rates by large retail firms, which exist in every city and sell everything from dry-goods to crockery and tea. For some time the different pharmaceutical societies and journals have been discussing different plans by which a profit might be made on these compounds; and various agreements have been made with the proprietary manufacturers, prominent among the plans being one by which a rebate is to be given to all retailers who sell at the regular prices.

Recently another question has received much attention. This is a fancied grievance on the part of the manufacturers that the druggists are in the habit of advising customers who ask for some particular brand of medicine to take a similar compound of their own manufacture, thereby saving money for both the apothecary and the patient. A statement that this was being largely done all over the country has found its way into many daily papers, apparently through the efforts of a bustling western advertising agent. The arguments advanced against this practice are in a certain way unique. They are, in short, that if a manufacturer of a patent medicine creates a demand for his compound by extensive advertising, it is against good business morals for any one by word or deed to do anything which shall injure his business; that is, no apothecary — we do not know whether this is meant to apply also to physicians — should advise his clients to abstain from swallowing a mixture, of the contents of which he is ignorant, or perhaps suspicious.

The retail druggists, through their societies and journals have shown indignation at this "charge of substituting," or more truly speaking, at this charge of dishonest dealing.

During the last month a sort of compromise on cutting and substituting has been reached, in the spirit of a plan recommended by the American Pharmaceutical Association. The wholesale druggists were represented by the National Wholesale Druggists' Association, and the manufacturers by the Association of Manufacturers and Dealers in Proprietary Articles. The manufacturers agree to sell only to those who agree to sell at the retail price, while the druggists agree not to substitute on such preparations as are included in the contract.

In no way, perhaps, can one better appreciate the truth of our opening sentence than by following these controversies in the pharmaceutical journals. A clearer idea is thus obtained of the enormous business which the patent medicine industry has achieved in this country than by a whole book of statistics.

#### MEDICAL NOTES.

THE POWER TO REJECT CANDIDATES. — An important suit involving the right to reject a candidate for admission to a medical society in New York, has terminated in the acquittal of the defendant, who was chairman of a committee on admissions. According

to the *Medical Record*, Dr. Robert B. Gould brought action against Dr. A. S. Hunter, Chairman of the Committee on Admissions of the Academy of Medicine, for slander as to plaintiff's professional standing, whereby his nomination to the Academy was barred. Although the utterance complained of would be ordinarily privileged as confidential, there was further charge of actual and express malice. The jury not only brought in a verdict for the defendant, as the plaintiff utterly failed to prove his point, but Judge Daly, in view of the groundlessness of the action and of the sacrifice of time and money in defending said action, granted an allowance of four hundred dollars to the defendant's counsel.

INSTRUCTION FOR THE ARMY HOSPITAL CORPS. — It is reported that the secretary of war has approved the formation of two companies of instruction for the hospital corps, each company to consist of about fifty men, who will be selected from civil life. Each company will be officered by three medical officers, a captain and two lieutenants, and have as the non-commissioned force three hospital stewards and four acting stewards. The duties will include the usual drills and examinations in professional subjects. After the men have become thoroughly familiar with their duties they will be assigned to posts for actual duty. One branch of the new school will comprise instruction in theory and practice of cookery, and it is expected that not only will the men of the hospital corps become proficient in this art, but that other enlisted men of the service can be included in this branch, and that the school will ultimately furnish skilled cooks to the line of the army.

THE PURITY OF THE AIR AT DIFFERENT LEVELS. — At a meeting of the Select Committee on House of Commons Ventilation, Mr. W. J. Prim described his experiments to determine the purity of London air at different elevations. He found that there were more smuts at high elevations than at low, but on a level of the court-yard there was a considerable quantity of dust. His conclusions were that the purest level was between thirty and forty feet from the ground, and that nothing was gained by going higher, unless it were practical to go very high, that is to four hundred feet.

THE SIMIAN TONGUE. — The correspondent of a daily paper writes that Prof. R. L. Garner, whose study of the language of apes was described in the *JOURNAL* of August 6th, is to go to Africa to make a more thorough investigation of the subject in the native woods of the gorilla and chimpanzee. He will take with him a large iron cage, constructed in sections, so as to be readily transported. Professor Garner proposes to occupy it himself, having set it up in the midst of the forest. It will be big enough to provide him with room to sleep and to study. Necessarily, the cage will have to be massively built, in order to defeat any efforts that may be made by gorillas to pull it apart. In that region the forests

at night are kept in an uproar by the howls of gorillas. These are the bachelors of the species, which are naturally disposed to postpone going to bed until morning. Here Professor Garner will establish his roost, and try to catch by ear a few suggestions of the language. He anticipates that the study he has already made of monkey talk will be a help. After acquiring by guess the meaning of a few words, he will make use of them by taking part in the howls himself. By day as well as by night he will make responses to the yells and cries of gorillas that he hears in the woods, and he thinks that in this way he will be able to attract certain individuals, especially females, about him, and intimacies may result which will afford most profitable opportunities for conversation. He will not venture out of his cage, however. Professor Garner will carry along with him eight phonographs which will be placed around the inside of the cage, with large tin trumpets fixed to their diaphragms and pointed outward to catch any words which the gorillas may speak near enough to be recorded.

#### NEW ENGLAND.

**DIPHTHERIA IN CONNECTICUT.**—In the monthly bulletin of the board, the secretary of the Connecticut State Board of Health says, that during the present year, up to the 1st of November, diphtheria has been one of the most prominent and fatal diseases in Connecticut. The mortality from it has been just double that from typhoid fever, and only three diseases, to wit, consumption, pneumonia, and infantile diarrhoea are more fatal. The feeble efforts which are made to control it have not been conspicuously successful. The failure is due to the want of an intelligent and efficient application of known means of preventing and restricting the disease. The conclusions of the paper on diphtheria in Massachusetts, by Dr. S. W. Abbott, which appears in full in this and the preceding number of the JOURNAL, are quoted and commended.

#### NEW YORK.

**HOSPITAL FACILITIES FOR THE TREATMENT OF DIPHTHERIA AND SCARLET FEVER.**—The Committee on Hygiene of the County Medical Society presented, through Dr. A. Jacobi, a report in reference to the unfortunate lack of hospital facilities in New York, for the treatment of diphtheria and scarlatina. Statistics showed, Dr. Jacobi stated, that within the last twenty-five years 60,000 persons had died from these two diseases, and the spread of such contagious affections was frequently promoted by the lack of intelligent and thorough disinfection. The disinfection of hotel rooms where persons had been sick with diphtheria, he said, was not as rigid as it should be, and he knew of rooms and suites of rooms, in some of the best hotels, in which there had been successive cases of diphtheria. With adequate means of treating such diseases in hospitals where the patients could be properly isolated, the dangers of contagion would be greatly lessened. As a result of Dr. Jacobi's report, a

resolution was adopted urging the establishment of more hospitals similar to the Willard Parker Hospital, where contagious diseases may be properly treated, and also the establishment of suitable asylums or refuges, where children who are in danger of exposure to contagious diseases in the the houses where they live, may be taken and kept until such danger has passed away.

**THE WATER-SUPPLY.**—The recent rains have caused an abundance of water in the Croton region, so that all the storage reservoirs in Westchester and Putnam Counties are full to overflowing. In consequence the pressure in the city mains has been increased to the regular strength, and the supply furnished is now once more 165,000,000 gallons a day.

**THE TELEPHONE FOR DIAGNOSIS.**—In the case of a child two years and a half old, suffering from membranous croup, intubation was successfully practiced recently by Dr. J. Mount Bleyer, but when he came to remove the tube he found that the tube had entirely disappeared. In the hope that it still remained in the upper air-passages he resorted to the use of a telephonic test to locate the position of the tube before resorting to tracheotomy, and the result proved very satisfactory. A delicate metallic probe attached by an electric wire, the other end of which terminated in a telephonic receiver, was passed down through the larynx, and as soon as it came in contact with the tube a distinct click was communicated to the ear through the receiver. The exact location having thus been determined, tracheotomy was performed and the tube extracted by Dr. Frederick S. Dennis, and according to the latest accounts the child was doing well.

**FRACTURE OF CERVICAL VERTEBRÆ.**—A case is reported from St. Luke's Hospital, Newburgh, in which a patient lived for eight days after meeting with a fracture of the cervical vertebra. The accident occurred from striking the head against a shed under which the man was driving.

### Miscellany.

#### MORTALITY IN DIFFERENT OCCUPATIONS.

M. BERTILON, in a paper presented at the Congress of Hygiene in London, shows the mortality of persons in different occupations based on statistics of the city of Paris. The average is made for each year of life, by which system different results are obtained than when the average age at death is taken as a basis. The highest rate is among cabmen, undoubtedly on account of their exposure to the weather. The drivers of other vehicles are more long lived. Saloon-keepers, although showing a high mortality, are longer lived than in England. The mortality is high where mechanics work in an atmosphere laden with dust, and especially if the dust is hard and gritty; metal-workers and stone-cutters show a higher mortality than bakers. Tailors and shoemakers show a mortality above the

normal, possibly because these trades are sought by men of weak constitutions. The trade of blacksmith, also, is apparently not conducive to long life. As in England and Switzerland, where similar statistics have been published, the longest lived persons are priests, gardeners and school-teachers.

In regard to physicians, the statistics of Paris differ from those previously obtained. The Parisian physician has a good prospect of a long life. This is, undoubtedly, due to the different life led by a city and by a country practitioner. It is to be noted that in Switzerland, although the doctors died young, their children have a low mortality. The length of life of the small class, which by reason of wealth have no regular employment, is below the average.

### THE TREATMENT OF HERNIA BY MEDIAN ABDOMINAL SECTION.

In the Section on Surgery, British Medical Association, Mr. Lawson Tait read a paper on this subject.<sup>1</sup> He believes that the certain radical cure of hernias can only be brought about by making a median incision and drawing the gut or omentum out of the sac from within, and then stitching together the internal opening through which the hernia occurred. He takes the ground that it will always prove an easier thing to reduce the gut by this method than by attempting to shove it in from the sac, even if the sac were adherent to its contents. His experience, he says, entirely supports this theory. Mr. Keely, of the West London Hospital, Mr. Jordon Lloyd, of the Queen's Hospital, Birmingham, and several other eminent surgeons, disagreed with the reader of the paper, in view of the fact that such obstruction, adhesion or devitalized condition of the gut might exist as would make it a dangerous and undesirable procedure to attempt to drag or put tension on the contents of the sac, especially where the bowel to be a part of the contents. Mr. Greig Smith and Prof. Bennet May agreed with Mr. Tait, in so far that they deprecated enlarging the tendinous aperture, which must be done in relieving strangulation by the older methods. In closing, Mr. Tait stated that the objections of the others were merely theoretical, and that they never occurred in practice.

### TYPHOID AND TYPHO-MALARIAL FEVERS.<sup>2</sup>

In 1889, the Michigan State Board of Health resolved that the local boards of health throughout the State be urged to second the action of the State Board of Health by making "regulations" declaring typhoid fever a "disease dangerous to the public health," which should be reported to the health officer in accordance with the law; also, that, in the opinion of this board, all cases of so-called "typho-malarial fever" should be reported to the local health officer, and the same precautions taken as in cases of typhoid fever; also, that all cases of fever of doubtful origin continuing more than seven days should be reported to the health officer, and precautions taken as in other diseases dangerous to the public health, such as typhoid fever.

Since this action by the State Board of Health it seems that a less proportion than formerly, of the cases of fever, are reported as "typho-malarial," and an increasing proportion of the cases of typhoid fever which occur are undoubtedly being reported to the State Board of Health. The local boards of health are beginning to co-operate with the State Board. Thus, at its meeting, October 16, 1891, the Board of Health of the city of Alpena adopted substantially the same resolutions as those adopted by the State Board, and restrictive measures for the prevention of typhoid fever are coming to be general throughout Michigan. There was need for it, because the vital statistics indicate that about a thousand lives a year were being lost in Michigan from this preventable disease.

### THERAPEUTIC NOTES.

**ANTISEPTIC ADHESIVE OINTMENT.**—The following is an antiseptic adhesive ointment used at the Hospital St André:<sup>1</sup>—

R	Zinci oxidi . . . . .	gr. lxxv.
	Zinci chloridi . . . . .	gr. xxviii.
	Gelatin . . . . .	℥ v.
	Aque . . . . .	℥ viiss. M.

The dressing protects the surface of wounds and dispenses with the use of bandages after operations. It is especially of service for the dressing of wounds on the face.

**A SIMPLE METHOD FOR RECTAL INJECTION.**—Mr. Jones Humphreys<sup>2</sup> has devised an apparatus consisting of a small funnel, a piece of elastic tubing one-half an inch in diameter, one and one-half feet long, about four inches of glass tubing (by which the descending fluid can be watched), and joined on to this an ordinary flexible catheter. The hydrostatic pressure is sufficient to send any fluid into the rectum, and no return of the fluid has been observed. The instrument is an improvement on the old enema apparatus in use. It is extremely simple, the patient being able to pass the catheter into the bowel without experiencing any pain or unpleasantness. The fluid is slow in its passage.

Deaths reported 3,221: under five years of age 1,115; principal infectious diseases (small-pox, measles, diphtheria and croup, diarrhoeal diseases, whooping-cough, erysipelas and fevers) 507; acute lung diseases 111, consumption 355, diphtheria and croup 263, typhoid fever 105, diarrhoeal diseases 79, scarlet fever 73, whooping-cough 21, cerebro-spinal meningitis 22, malarial fever 17, measles 8, erysipelas 6.

From scarlet fever New York 16, Chicago 15, Philadelphia 7, Brooklyn and Pittsburgh 9 each, Baltimore 6, Milwaukee 7, Cincinnati and Lynn 2 each. From whooping-cough New York 4, Chicago and Philadelphia 4 each, Washington 2, Brooklyn, Boston, Baltimore, Cleveland, Pittsburgh, Milwaukee and Springfield 1 each. From cerebro-spinal meningitis Chicago 6, New York and Brooklyn 1 each, Worcester 2, Cleveland, Washington, Fall River, Taunton, Gloucester and Fitchburg 1 each. From malarial fever Brooklyn 5, Philadelphia and Baltimore 2 each, New York and Cleveland 2 each, Nashville and Charleston 1 each. From measles New York 1, Chicago 2, Brooklyn and Baltimore 1 each. From erysipelas Chicago 3, Boston, Baltimore, Cleveland, Worcester and New Bedford 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,105,108, for the week ending October 31st, the death-rate was 18.1. Deaths reported 3,264: acute diseases of the respiratory organs (London 271, diarrhoea 97, whooping-cough 13, fever 56, diphtheria 44, scarlet fever 37, measles 5).

The death-rates ranged from 10.8 in Brighton to 25.0 in Sunderland; Birmingham 18.7, London 15.1, Bristol 19.7, Huddersfield 12.0, Inver 21.0, Leeds 17.8, Leicester 15.4, Liverpool 21.9, London 16.7, Manchester 21.3, Newcastle-on-Tyne 22.2, Nottingham 15.9, Sheffield 17.9, Wolverhampton 20.8.

In Edinburgh 13.1, Glasgow 26.1, Dublin 21.2.

**OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 21, 1891, TO NOVEMBER 28, 1891.**

The leave of absence for seven days, granted CAPT. ARTHUR W. TAYLOR, assistant surgeon, U. S. A., is hereby extended twenty three days.

Leave of absence for three months, with permission to apply

for an extension of one month, is granted CAPT. MARSHALL W. WOOD, assistant surgeon, U. S. A.

Leave of absence for twenty days is granted CAPT. WILLIAM R. HALL, assistant surgeon, U. S. A.

The leave of absence, on surgeon's certificate of disability, granted CAPT. MARLBOROUGH C. WYTHE, assistant surgeon, U. S. A., is extended three months, with permission to enter the Army and Navy General Hospital, Hot Springs, Ark.

**OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 28, 1891.**

MIDDLETON SEMMES GUEST commissioned an assistant surgeon in the Navy, November 19, 1891.

WM. MARTIN, surgeon, ordered to the U. S. S. "Thetis." GEO. B. WILSON, assistant surgeon, detached from U. S. S. "Thetis," ordered home, and granted two months' leave.

**SOCIETY NOTICE.**

**BOSTON SOCIETY FOR MEDICAL OBSERVATION.**—A regular meeting of the Society will be held at 19 Boylston Place, on Monday, December 7th, 1891, at 8 o'clock.

Dr. W. F. Whitney will read a paper on "Fat Embolism"; Dr. E. N. Whittier will read a paper entitled "Internal Antisepsis." Dr. H. C. Ernst will open the discussion.

JOHN C. MUNRO, M.D., Secretary.

**RECENT DEATHS.**

LEVI IVES, M.D., of New Haven, Conn., died December 1st, aged seventy-five. He graduated from the Yale Medical School in 1848.

G. D. DUNHAM, M.D., formerly Assistant Surgeon, U. S. A., died in Plunkham, N. Y., November 23th.

THE DIAGNOSIS AND TREATMENT OF HIP-JOINT DISEASE.<sup>1</sup>

BY V. F. GIBNEY, A.M., M.D., OF NEW YORK,  
*Professor of Orthopedic Surgery, New York Polytechnic; Surgeon-in-Chief to Hospital for the Ruptured and Crippled, New York, &c.*

THE subject has become a hackneyed one so far as I am concerned, and I find it difficult to present anything new or interesting. Cases that have been carefully recorded sometimes furnish instruction, and I have decided to make this a clinical report, and, from the histories here recorded, will attempt to emphasize certain points in diagnosis and treatment.

CASE I. Disease in first stage; prompt protective treatment; splint continuously for one year; result, a cure with perfect restoration of function.

On the 11th of April, 1887, a boy, four years of age, living in Minneapolis, Minn., came under my care for chronic osteitis of the hip, right side. The maternal family history was decidedly tuberculous. I recorded at the time a number of details confirmatory of this diathesis. The patient himself, when ten months of age, had whooping-cough, and it was many months before he fully recovered. Indeed, his mother thought he had never recovered. He had been treated for catarrhal trouble as a result of this cough. For at least a year before he came under my observation, a peculiarity in his gait had been noted. He favored the right limb, turned the toe in while walking. The mother was positive that at no time was he free from this slight limp. She was equally positive that he had had no pain for at least six months after the first appearance of the limp. Then, while wintering in Florida, he complained of pain in the groin. Shortly after the occurrence of the pain, he had a fall, which made him more lame than usual. His pain was quite severe; immediately after the fall, he complained of his knee. A physician in St. Augustine diagnosed hip disease. The little fellow was unable to walk for three or four days. Then he got on his feet again, and had been free from pain ever since.

At the time of my examination there was a slight change in the ileo-femoral crease compared with that on the other side. There was no atrophy of the limb, no joint tenderness, no fulness about the joint, no glandular enlargement. His limb was parallel with its fellow, with the exception that, as he stood, he toed-in a little. On flexing the thigh to an acute angle he showed reflex spasm, that is, he resisted, winced a little, and by flexing the left limb, I got no such sign. I could rotate the right limb quite as well as the left, but could not abduct completely without encountering this same reflex spasm. I repeated these tests several times with uniform results. Taking into account the history, the exacerbation during the winter, the persistence in lameness, and the few signs found at this examination, I expressed my belief that osteitis was present, though deferred treatment until after another examination, which was made four days later. Examination then revealed the same signs. I learned at this time that a friend of mine, a distinguished orthopedic surgeon in New York, had expressed the same view, and had advised apparatus.

It was the first of May before I succeeded in getting

a splint supplied, owing to certain unavoidable delays. The apparatus is the one commonly used, and consists of a stem, pelvic band, perineal straps, and high shoe on the sound foot. This is a perineal crutch practically, and is intended to protect the joint against trauma. The child walked on his perineum. I had some difficulty in carrying out the details because of certain chafing of the limb that occurred from the adhesive strips. It was difficult to make the mother appreciate the importance of protecting the joint at this stage. Still, by dint of perseverance, I succeeded in overcoming all obstacles and protected the joint until the summer of 1888. The apparatus was employed night and day. The first few weeks it was not changed except under my personal observation, then the limb was steadied. Later on his mother was taught how to change the adhesive plasters.

At my last examination there was no sign of disease present, the apparatus was removed, and he walked without any lameness. I saw him a year later. There had been no recurrence whatever, and the case has remained cured.

CASE II. Disease in early stage; prompt application of protection-splint; not an untoward symptom afterwards; apparatus for at least eighteen months; result, cure with perfect restoration of joint functions.

On the 7th of January, 1888, a boy, eight years of age, was referred to me by Drs. William T. Lusk and William H. Flint. His history was briefly as follows: Two years previously a slight limp, right side, was observed. He had no pain. This lameness lasted a month or so, the boy complaining occasionally of a slight aching in the joint. After that it was thought that he did not limp for a period of at least eight months. Then, without apparent cause, he began to go lame again, got better, but had never been from that date to the date of my first examination, free from a halt. In November, 1887, he came under orthopedic treatment, wore a short splint; but the joint did not seem to be sufficiently protected, he had occasional pain, and for this reason was referred to me for treatment.

I found him well-nourished, quite active, limp very well marked; nates flattened; thigh three-quarters of an inch smaller than its fellow. Movements when carried to extreme limits in all directions produced reflex spasm, particularly in rotation. There was no infiltration about the joint, no bony enlargement, no joint tenderness even. The soreness was mostly peri-articular. The limbs were equal in length. The diagnosis was osteitis of the right hip, chronic and probably tubercular.

I had no difficulty in persuading the father that absolute and unconditional protection was required. So we lost no time in applying a long traction-splint. From that date he never had any more pain. The splint was discarded on November 1, 1890. At that time the extension was perfect, flexion perfect, abduction not quite perfect, but no reflex spasm excited. The limbs were equal in length; there was one inch and a half atrophy of the thigh; knee action was good. I have had an opportunity of examining this boy from time to time up to the present summer, and his good condition remains unimpaired. There is no lameness whatever, he is very active, and leads an out-of-door life.

These two cases are presented to illustrate the early diagnosis made upon the existence of certain signs,

<sup>1</sup> Read before the Fairfield County (Conn.) Medical Society, at Stamford, October 13, 1891.

and further to illustrate the efficiency of protective treatment. The result in each case was perfect. The treatment has been very simple, but extended necessarily over a long period of time. This was done because the pathology which I adopt is this,—a tubercular inflammation in the epiphyses, near the epiphyseal line, behaving exactly as similar foci do in the lung, subject to the same influences of trauma, and resolving, if sufficient protection is given and if good hygienic surroundings can be obtained.

**CASE III.** Disease in second stage: plaster-of-Paris spica first; protection splint for two years; abscess toward the close of second year; aspirated, subsequently opened spontaneously, soon closing; Dowse convallescening splint; excellent result, with very little lameness, a half-inch shortening.

On the 9th of July, 1884, a boy, seven years of age, was referred to me by Dr. Whitbeck, of Rochester. He began to limp in the spring of 1884. At that time he had rather a sharp exacerbation of pain. No cause could be assigned, in the way of trauma, at least. A second exacerbation came on a month or two later. His family history was fair. A trace of tuberculosis was found.

At the time of my examination there was one inch practical shortening, which is the shortening found by measuring from the umbilicus to the internal malleolus. There was no real shortening. By this I mean no difference by measuring from the anterior superior spines to the malleoli. There was an inch atrophy of the thigh. The hip was locked at an angle of  $150^\circ$ , practically no motion. There was no joint tenderness, but considerable periarticular tenderness, as evinced by pressure and attempted movement. There was fullness in groin and above trochanter major; pain at night, though no screaming during his sleep.

I applied at once a plaster-of-Paris spica bandage until I could get a splint ready, which was on the 25th of July. The perineal straps clafed a good deal, and it was some time before he wore the splint with comfort. By the 1st of August, 1884, he was getting about very comfortably. He had no pain during the fall of that year; the deformity became less marked. A year later it was necessary to lengthen his splint, and all the attention he required was an occasional readjustment of the adhesive straps. In 1886 he developed an abscess on the outer side of the thigh. This was aspirated. He suffered considerably during the formation of the abscess. It finally opened spontaneously, and closed within a few months. In the spring of 1889 he had so far recovered that I applied a jointed splint, what is known as a Dowse, which is a long splint with the addition of a joint at the knee, secured to the thigh and calf by a lacing, but not used for traction. This was discarded the following year, 1890. From that time to the present he has had no recurrence of symptoms. I have examined him once in about six months merely for record. My last examination was on the 15th of September, present year. There was no practical shortening, one-half inch real shortening, one-and-a-half inch atrophy of the thigh, one inch of the knee and three-quarters of the calf. The thigh could be extended to  $160^\circ$  and flexed to  $150^\circ$ . He had very little lordosis, stood with limbs very nearly parallel. He goes to school every day, walk with a very slight limp, and the result altogether is very good.

**CASE IV.** Disease in second stage; protection

splint for a year; then abscess, which was opened, with prompt healing; apparent cure; then relapse, with deformity; osteotomy for correction of deformity; excellent final result, almost a perfect cure.

A boy, two years of age, was referred to me on the 15th of July, 1885, by Dr. Hungerford. This child was one of six. Had always been weak on his limbs, so his mother reported. Had measles in December, 1884, was a long time convalescing, had phlyctenular conjunctivitis. He favored this left limb for five months prior to the date of my first observation. Two weeks before I saw him he fell, spreading his limbs apart. Came in the house crying very much, and was lamier than usual. A few days before I saw him he was apparently unable to walk. He held his limb flexed at an angle of about  $150^\circ$  and resisted all movements. The parts were very sensitive. A diagnosis was made without hesitation, a splint was applied, and he did well until early in the following spring, when an abscess appeared. It was opened, thoroughly cleansed, and an effort made to secure asepsis. This was not satisfactory, but the traction afforded the limb seemed to suffice, the discharge became less, and in June, 1887, there remained only a small sinus. This sinus closed during the summer, and on the 16th September 1887, it was entirely healed. The angle of deformity was about  $175^\circ$ . The limb could be abducted over a small arc and rotated over about one-half the normal arc; thigh could be flexed to about  $150^\circ$ . The limbs were equal in length. There was an inch and a half atrophy of the thigh, three-quarters of the knee and one inch in calf. He continued the use of his splint until September 30, 1890, when the adhesive strips were abandoned and the splint was made into a kind of semi-caliper, which consisted of the same apparatus, the foot-piece being converted into a stem which passed through a tube in the heel of the shoe. He wore this for some months and then abandoned all treatment. This was without my advice. On the 22d of May, 1891, I found that he had a deformity which was unyielding. So, on the 24th of June, I attempted to correct this under ether, by manual force, but failed; then divided the femur below the trochanter minor and brought the limb down into normal position. He left the hospital on the 16th of July, with limb down to an angle of  $170^\circ$ . On the 6th of August I found the limbs parallel, angle of greatest extension about  $175^\circ$ , one-half inch shortening, real, no practical shortening. September the 29th, I saw him again, and his limb could be extended to  $180^\circ$ . He walks well; is wearing a convalescing splint.

**CASE V.** Disease with long first stage in an adult; *brusment force*; aggravated case; traction in bed, then splint gave prompt relief; prolonged use of splint; abscess aspirated, finally opened; second one disappeared under pressure: case convalescing; patient attending to business all the time.

On November 25, 1887, Dr. Robert F. Weir asked me to see with him in consultation a gentleman, twenty-two years of age, who had been an athlete, and who was suffering at the time of the examination from what we diagnosed as chronic osteitis of the left hip. The patient was a hearty, robust-looking man,—family history on one side tuberculous. Four years before, while playing foot-ball, he sprained his hip. Thinks he was annoyed for two or three months thereafter with a little stiffness at night. At the end of this two or three months this stiffness passed off, and it was

almost a year later that he was troubled again with a recurrence of symptoms. So that he dates his lameness to the beginning of this second attack. Then he consulted a distinguished surgeon, now passed away, and a strain was recognized, the patient advised to keep quiet. He did not follow instructions, but continued in milder athletics until June, 1887. Dr. Weir saw him at this time, found a little swelling in the Scarpa's space. The aspirator needle was inserted with negative results. The thigh could be flexed to 90° then, quite easily, and the other movements were equally good. Expectant treatment was employed. The patient went to the country and played tennis during the summer. In the early fall he became anxious again and two or three surgeons were added to the consultation, Drs. Sands and Bull. Traumatic hip disease was diagnosed, and it was advised that the adhesions about the joint be broken up, under ether. This was done about three weeks prior to the date of my call. Considerable inflammatory reaction followed.

We found limbs parallel, but the slightest attempt of movement caused great pain referred to the anterior surfaces of the thigh and down to the knee, with general infiltration about the hip, though no distinct tumor about Scarpa's space. There was no atrophy of the limb. Limbs equal in length. Spinal column quite flexible. The diagnosis was made of osteitis, splint was advised, and the treatment begun at once, the weight and pulley being used, pending the completion of the splint. This was applied December 17th. He was not allowed to get out of bed for at least a fortnight. He got relief at once. On February 2, 1888, he was going about using the splint, with axillary crutches. Had an occasional starting pain at night, but nothing of any serious moment. He went to the country in the following summer, and in the spring went to the University of Virginia, where an abscess developed on the outer side of the thigh about the middle third. This was aspirated by Dr. Dabney, of the University, but with rather unsatisfactory results. I saw him in the fall. The abscess had opened spontaneously. Simple dressings were applied, and he continued to go about as usual. During the winter of 1888 and '89 he had a hemorrhage one night, which was not repeated. Dr. Loomis has examined him from time to time since then, finding nothing to account for this hemorrhage, but advising that he avoid too much exercise and rely on climatic influences. July 5, 1889, the sinus was about closed, but on the inner side of the thigh was a distinct swelling, with fluctuation. Dr. Weir saw him with me, and advised against operative interference. By the 21st of September this tumor was reduced to one-half its original size, general health was good; the patient was working at a desk in Wall Street. On the 7th of February, 1890, the report was made that his general health was very good, weighed 190 pounds, a gain of twelve pounds in the last six weeks. There was no discharge from the old sinus, no fluctuation of the tumor on the inner side of the thigh. The thumb could be thrust well down into the old sac, which seemed to be quite empty. Rotation of the hip very fair, limb well developed. No infiltration about the hip, no tenderness or soreness. On October 2, 1890, there was no sign of any abscess; limbs equal in length; still using his splint; still attending to his business. The notes made from that time to the present show very little alteration. When I last saw him, which was August 26th, I advised that the splint be

discontinued at night. I expect during the winter to apply a jointed splint and to remove the high shoe from the sound foot. The case is certainly convalescing, and the outlook for a useful limb is excellent.

CASE VI. First diagnosis sacro-iliac disease, right side; later, hip disease, left side; later still, hip disease, both sides, abscesses, right side; progressive septicaemia in spite of rest and protection-treatment; excision as *dernier ressort*; excellent result.

On January 22, 1890, a boy, nine years of age, from Poughkeepsie, New York, was admitted to the hospital. He had been under observation in the outpatient department for three or four weeks, a diagnosis having been made there of sacro-iliac disease, right side. The diagnosis was based upon tenderness, peculiarity of gait, persistent pain over the sacro-iliac junction. The hips had been carefully examined with negative results. No reflex spasm whatever in any direction. The mother was advised to put him in hospital and allow us to trephine at the sacro-iliac junction and "nip" the disease "in the bud." Accordingly she admitted him.

There was no special fulness about this region, and it was decided to keep him in bed a few days and study the case more carefully. This tenderness persisted. The boy was in very good condition. After a week's time a blister was applied and operative interference was postponed.

Suddenly, one morning, after he had been in the hospital about three weeks, he complained of pain in his left hip and knee. Then we learned from the mother, who made a visit that day, that he had complained of pain in the left limb in the latter part of September, 1889, that he was quite lame for awhile, but the symptoms soon passed off and she gave no further attention to this joint. The boy was examined quite carefully, and the left side was found to be a half inch smaller than the right. With this exception there were no signs. A few days before this pain came on in the left hip and knee, he complained of pains about the left sacro-iliac junction and there was tenderness here. It was recorded on February 15, 1890, that he could flex and extend both hips perfectly, abduction and adduction of thighs good, though there was this same peculiar limp referred to the sacrum.

It was noted March 4, 1890, that there was some reflex spasm about the right hip, and on the 12th, pain in the right knee. The pain about the sacro-iliac junction had disappeared. On the 19th of March, the pain persisting in the right knee, he was put up in a plaster-of-Paris spica bandage, traction being made by weight and pulley in bed. March 29, 1890, the left hip was examined carefully without signs. On the right side the glands were infiltrated, there was fulness in iliac fossa, as well as on the anterior aspect of the thigh. A hip-splint was applied to this side, and the boy was put in a reclining chair. Next day he was suffering a good deal and was put to bed.

April 8th, the signs returned in left hip again, and the movements were all limited, so that a double plaster-of-Paris spica bandage was applied. On the 26th of May, 1890, the plaster had chafed a good deal about the bony prominence and the boy was losing flesh. He had a high temperature and he was put on the Cabott frame. A note was made August 22, 1890, that a large abscess had formed. It was aspirated on this date. Three or four days later it was

aspirated again, and about eight ounces of pus were removed. On September 30th, it was noted that the abscess had opened at the point where the aspirator needle had been inserted, there was a sinus, and on this date he was put under ether, the sinus was enlarged, sac pretty well evacuated, and the cavity well washed out and drained. He got very little relief after this, and on December 23, 1890, it was noted that he was suffering considerably, that the discharge was profuse, that the boy was emaciating, in spite of all the traction on both limbs in bed, that he was losing ground. So the abscess was thoroughly cleansed again under ether, and an attempt made to reduce the discharge. At this time all the sinuses about the sacro-iliac junction had disappeared, and it was a question, now, whether we would be able to save his hips. On January 28, 1891, another abscess was found about the right hip. This, in a few days, opened spontaneously. The drainage was good, parts were dressed every two or three days, was taking tonics and stimulants, traction was kept up unremittently.

February 10, 1891, he had become so thin, was suffering so much, his temperature continued without any abatement, that, as a *dernier ressort*, his right hip was excised. There was very little left of the head of the bone. Acetabulum was scraped, no attempt made to get thorough cleansing of cavity, but the operation was done rapidly, the offending portion of bone removed and cavity packed with iodoformized gauze.

In this connection it may be interesting to note that on the 29th of January, 1890, we began to take his temperature night and morning. On this date it was 100.2°, on the 5th it was 101.6°. It ranged from this down to 98.4° until the 5th of March, when it reached, in the evening, 103.8°. On the 10th, it was 103.6°. On the 14th of October, it was 104°. On the 12th of November, it was 104°. It seldom fell to normal, only on two or three occasions in six months. On the 19th of February, 1891, it was 100.8° in the evening. This was the day of the operation. It reached 100.4° next day. It did not get above 100° until the 16th, when, in the evening, it reached 101°, then fell to 99° next day, and continued under 100° until the 8th of April, when it was 102°. On the 17th it fell to normal, and has remained normal up to the present time. That is, we kept a faithful record of his temperature from January 29, 1890, to April 22, 1891, at which time the sinuses were discharging very little, and he was evidently improving. He was still kept in plaster-of-Paris from the ankles up to the free ribs, the discharge was growing less and less, and every prospect for recovery was entertained.

He was sent to Saratoga in the early part of July, 1891. The sinuses were dressed very infrequently during the summer. Toward the close, on his return, he was stout, hearty-looking, and there was only one sinus, in front, which was discharging, and this was soon covered by a scab. At present writing everything is closed, plaster has been removed, and the examination recorded September 16th, showed that in the right limb, angle of greatest extension at hip was 180°, angle of greatest flexion about 150°. The left thigh could be extended to 180°, and flexed to 135°. Abduction and adduction were about one-half normal. There was a little thickening about the right hip, but no fluctuation.

He is to be fitted with a Thomas hip splint, to extend from the scapula down to the calf, this splint to

be applied to the right side merely to retain limb in good position. The left limb is very serviceable. Is to have a pair of axillary crutches, and as the right limb is about one inch shorter than the left, no high shoe is to be employed. The recovery is, therefore, excellent.

All of these cases, with the exception of the last, are reported to show the comfort with which patients get on, even if they have abscesses, when the joint is protected. Case V shows that the disease may develop in the adult and pursue about the same course that it does in childhood. Case III shows that the deformity can be corrected by an osteotomy, and Case VI is reported to outline the indications for excision of the hip, and a careful study, I think, will bring out points, not only in favor of excision, but in favor of protecting the parts for many months after the operation, and even after all sinuses are closed.

The conclusions, I think, that may safely be drawn from these few cases reported in detail, are:

- (1) An early diagnosis can be made by any one who examines the case carefully, and who familiarizes himself with the functions of a sound joint.
- (2) The necessity of regarding a case as chronic and therefore requiring prolonged protection of the joint.
- (3) The comfort that any patient may derive from an apparatus that is made to fit.
- (4) The benign progress of a case thus protected.
- (5) The importance of maintaining parallelism and equality of the limbs at all times and under all circumstances.
- (6) The advantages of an out-of-door life, which cannot be secured by bed treatment.
- (7) The necessity for excision of the hip when well directed efforts at securing rest and protection to the joint have failed.

I have not attempted to give the details of treatment, have said nothing about how the splint should be applied, where it should be obtained, and what care is required during the whole course of treatment. The average practitioner should know principles, should be a good diagnostician, and should understand the pathology of the diseases he is called upon to treat. Details can be learned from the text-books and current literature.

---

The following is taken from the Supplement to the *British Medical Journal*: "Under the title 'Cæcitas Syllabaris et Verbalis, sed non Literalis,' Professor Ivan P. Mierzowski, of St. Petersburg, describes in the 'Vestnik Klinicheskoi i Sudebnoi Psikiatrii i Nevropatologii,' Vol. II, 1891, a case of peculiar word blindness with normal letter vision. The patient who was a very nervous medical man, noticed that he was unable to read, though he could distinctly differentiate letters, and his sight was otherwise good. At present, examination shows that he actually can differentiate every individual letter, but utterly fails to combine letters into syllables or words." We feel obliged to confess that while reading the first few lines of the above clipping, we were affected by the same symptoms. Our greatest surprise is that in Russia these symptoms should be so rare as to be deemed worthy of mention. In looking over Russian literature we have even doubted whether we were possessed of "normal letter vision."

ATROPHY IN JOINT DISEASE.<sup>1</sup>

BY E. G. BRACKETT, M.D.

THE value of any symptom lies not only in its uniformity, but in the definite understanding of its etiology, and of the relation of its occurrence to the pathology of the disease. The following paper has for its object the consideration of the relation of atrophy, both as a symptom, and a result of joint disease. The constancy of its appearance and its value as a diagnostic sign, is never questioned, but this relation to the disease, especially in its etiology, has not received particular attention from a purely clinical standpoint, but has rather been ascribed to those causes suggested by experiments, but which in reality were but little more than illustrations of a well-known clinical fact that this atrophy does occur in all forms of joint disease. There have been various theories advanced to explain the method of its occurrence, and which have at times, been more or less generally accepted. Two have, of late, at least, received but little attention, and were based on the propagation of the inflammation, one considering the wasting due to the extension of the inflammation of the muscle, and the other (advanced by Sabourin) to the extension of the inflammation to the nerve filaments and its propagation through them, molecule by molecule along the nerves, resulting in the wasting of the muscles supplied by them. Against these, there is not only the fact that it does not correspond to the clinical course or to the distribution of the atrophy, but also, that examination of these structures fail to show evidence of any such change.

The theory which has found the most support, supposes a nervous influence exerted through the spinal cord, that is, a reflex. Vulpian was the first to bring out a purely nervous reflex theory, and says: "In the majority of cases it must be classed among the atrophies called reflex, that is, among those which are a result of a change in such regions of the gray matter of the spinal cord, produced by irritation of the peripheral ends of certain sensitive nerves." What this change may be is not distinctly stated, but rather classed among the indefinite changes, which, to explain a clinical fact, were supposed to exist.

Charcot inclines to this theory, but gives a more definite description of the changes which he considers to occur. It so nearly resembles the reflex theory of Vulpian, that it is practically but a modification, or elaboration of it. He considers it as a spinal affection, consisting of a sort of stupor, or inertia of the cellular substance, and which is brought about by the irritated articular nerves through which the joint lesion has reacted on the spinal centre, and there modifies the centres in the spinal cord, which preside over the nutrition of the muscles and the motor nerves. He claims the existence in the cord of a connection between the cells of origin of articular nerves and of trophic and motor nerves of the extensors, and so that when other than the extensors are affected, the irritation arising in the articular nerves has spread itself by diffusion to the muscles.

These are based on the assumption, that the morbid process in the joint exerts an influence on the trophic centres in the cord, through the irritation of the nerves. The statement is purely hypothetical, and adopted

rather because it seems to furnish an explanation, and not because it is borne out by pathological facts. On the other hand, it implies the absence of a pathological change, which, if true, does not admit of proof.

In view of this theory numerous experiments have been carried out, and which have been urged as proof of this mode of causation. Prominent among these are those of Valtat, and of Cazin and Duplay. They illustrate a fact well established by clinical evidence, that in acute joint diseases, atrophy occurs, but as there were no control animals, it can hardly be claimed that they do more. They are of value in determining that the atrophy is a simple one, and not attended by a pathological change, either in the muscle itself, or in the nerves or spinal cord. They do not show any definite proportion between the severity of the articular disturbance produced, or its duration.

These were all acute traumatic lesions induced in healthy animals, which were kept in more or less confinement. On the other hand, the cases seen in the clinical aspect are by a very large majority chronic, running a slow course with occasional exacerbations, but which occur usually after the establishment of the disease and not at its onset. They are of value for the purpose for which they were conducted, but they in reality have but little bearing on this subject as it appears to us clinically. There is so decided a difference between the course of an acute and a chronic joint disease that they cannot be brought together for comparison.

If it is to be grouped among the valuable diagnostic signs, its relation to the disease becomes of decided importance. If it is directly dependent on the joint disease, and the influence exerted through the nervous mechanism, there should be a somewhat constant relation between the course of the disease and its development. But since these theories are not based on pathological findings, we must turn to clinical evidence to confirm them. For this we have the fact in all forms of joint disease of the occurrence of an atrophy to a certain extent, but beyond this there is little to uphold them. We find that the degree of this varies to a wide extent, even in the same stages of the disease, and in cases of long standing to affect all parts of the limb, including the bones. It is also often noted that this atrophy does not bear any constant relation to the severity of the articular disease, to its duration, or to amount of pain, and the grouping of some of these facts show that there must be other factors which have a more or less constant influence on the causation of this condition.

In considering the influence of the severity of the disease, we must disregard those cases running an active virulent course, since in them are all the conditions which are to be considered. But in the usual case running a mild course without the persistence of active symptoms, we find so great a variation of this condition that there must be a most potent factor in its course besides an irritative nervous influence. Thus we often see in untreated cases, which have been allowed to use the leg, an atrophy which is only slight, but which is developed to a usual amount when the limb is immobilized in the course of treatment. On the other hand, cases which have early been immobilized will often show a decided atrophy, and this in the absence of acute symptoms. And also when all movements of the limb have been prohibited, as by the use of the plaster spica or the Thomas splint, the degree of

<sup>1</sup> Read before the American Orthopedic Association, Washington, September 22, 1891.

atrophy, is much greater than with the use of apparatus allowing more freedom. That it is not due to the pain, is shown by the fact that many of these cases, in which the atrophy is decided, pass through the whole course of the disease with but very little, and only occasional, pain. Were the irritative influence of the inflamed joint the chief factor in occurrence of this wasting, these variations could not exist. In addition, if due to this cause, nerve irritation should react more particularly on those parts connected with the joint. In place of this there is an atrophy, nearly, if not quite, evenly distributed over the entire limb, and although it has been stated by some experimenters, that the extensors are first involved, and to a greater degree, the clinical evidence will hardly bear this out. If this condition exists at all, it is to so slight a degree, as to be of no clinical value.

The active factor which seems to bear the most constant relation to this condition is the amount of use allowed, or possible, to the limb. This theory of disuse has received but little attention, and has usually been dismissed by the various authors with the mention that it is not sufficient to explain the condition; but that it holds the most important place in the etiology. I feel we are justified in assuming from our clinical evidence, not only from that which is seen in the early stages of the disease, but even more from the changes which occur later during the periods of growth. In these cases in the first stages of joint disease, we must estimate the effect of a partial disuse by comparison with other conditions which are met with at the same time, and it has been chiefly argued that it is not sufficient to cause the difference which is found to exist. Therefore, the relative effect of the various influences which are met with, can be estimated only by the comparison of the degree of this atrophy under these influences which occur most frequently and uniformly. Thus, we see that there is none of those factors, the presence of which is followed constantly by any definite degree of wasting, except this one of disuse. For cases with pain and with evidence of active disease show, at times, decided atrophy, and again, but little. On the other hand, a decided atrophy appears when there has been none of the signs of active disease. For example, I have the measurements of a case, in which the sensitiveness of the joint compelled the treatment on a frame from the beginning of the disease, which appeared suddenly. In this, both limbs were confined nearly to the same degree. The difference in measurement of the thighs was but one-half inch, and of the calf one-quarter inch, after several weeks of this condition, while in another, in which there had been scarcely any sensitiveness or pain, but the treatment had been the confinement of the limb in a Thomas' splint, the difference was two and three-quarter inches in the thigh and one and one-half inches in the calf.

Illustration of the direct result of complete disuse, is a case in which there had been the usual history of a slowly beginning hip-disease, but the child, an active boy of ten years, had been running about at will. At the beginning of treatment the atrophy was slight, under three quarters of an inch, thigh and calf, although there was a distinct articular disease. A plaster splint was applied, and on its removal after one month, the atrophy of the whole limb was so decided, that the parent were with difficulty persuaded to allow the plaster to be removed. There had been no increase

in the disease, as shown by examination of the limb or by the subjective symptoms.

But the objection may still be urged that, although this reflex nervous disturbance may not meet the conditions under which this atrophy is found, the disuse is not sufficient to cause this amount. But in two conditions we have illustrations of this, and under which we must look only to this cause for the difference in size,—so-called functional diseases and congenital dislocation. In the former, there is the limited voluntary use of the limb, but no diseased articular structures. It is usual, however, to find an atrophy of the whole limb which is not present at first, but is developed during the course of the affection; for instance, a child of seven, of a distinct nervous temperament, after three months of this affection where use of the limb had been allowed, showed a difference of one inch in the thigh, and three-quarters of an inch in the calf, which in a month after unrestricted use of the limb was begun was diminished one-half. In the instance of congenital dislocation we find a difference in proportion to the usefulness of the joint, and with a very loose joint the loss of development is decided, involving the entire limb uniformly; for instance, a child of three, having so little impairment that only a slight limp was perceptible, showed a difference so slight that was more easily determined by comparison of the appearance of the two limbs, than by measurement. Another, where the laxity interfered decidedly with the usefulness of the limb, showed a difference of three-quarters of an inch of the thigh, and one-half inch of the calf. Whereas another child, of eleven years, in whom the limp was painfully prominent, had a difference of one and three-quarter inches in the thigh, and seven-eighths of an inch in the calf. Therefore, I think that in view of these and of the other clinical facts, this factor cannot be dismissed with the statement that it is not sufficient, but must be ranked as the important one. And when we consider the physiology of muscular nutrition, it is in direct accordance with this method of its causation. The maintenance of the normal blood-supply is the essential factor, both of the nutrition and the development, and it is regulated mainly by the activity. The contraction of the muscle is its respiration, and has been found to be attended by a tissue change (obtained by examination of the return blood) and that there exists a direct relation between this and the repair or nutrition. In other words, the muscle depends on its work for the maintenance of its fully developed working condition. Deprived of this, it suffers in proportion.

If the disuse has so great an influence in the occurrence of the atrophy in the early stages, the results of its influence can hardly be less decided in the later, and becomes at this time most important. If we are correct in placing the element of use in this prominent position among the etiological factors, we should find later in the disease, the further evidence of its influence on the development of the limb. If due to the other causes there should be an impaired development in which those parts diseased should hold the most prominent place, and in proportion to the severity of the disease, but if in the greater measure due to the lack of natural use, we must look to a general deficiency of development of all parts involved in this temporary confinement. For this we must look to the condition of the limb after many months of treat-

ment, and in doing so, the most prominent condition is that of shortening and muscular wasting, the most valuable for us in this particular, being the shortening, omitting those cases in which there has been such a displacement of the bone as to alter the usual anatomical relations.

There are three factors which can be considered in the etiology of this condition: (a) Bone destruction; (b) Reflex nervous influence, that is, an inhibition of nutrition; (c) The effect of immobilization. The two former need but a brief mention. That which occurs from destruction of the head of the bone is doubtless but very little. In the first place, the anatomy at these ages is such that an extensive destruction of the head is attended with but slight loss in length, and even were there such loss, it would be shown by measurement of the bone; but from a large number of observations, I have found that this does not exist, and neither is the amount determined by the suppurative process.

Were this due to the reflex inhibitory influence from the irritation of the disease on the neighboring parts, then in those cases in which the disease early becomes quiet, and remains so, there should be but little loss of growth, and this loss should be confined to the vicinity of the affected joint, neither of which is the case. In place of this we find a loss of growth, involving the whole limb, almost equally distributed, and this influenced more by the amount of use of the limb than by any other factor. The evidence of this is, that in addition to the slight degree of atrophy which is present in all forms of joint disease and in all joints, the degree of this is proportionate to the amount of use which has been allowed the limb, and with uniform distribution over both of the bones and soft parts of the whole limb, and the existence of the same condition, under other circumstances, when in the absence of disease, the limb has been restricted in its use.

To illustrate the general distribution of this lack of growth the following observations were taken. These were made in cases of chronic hip disease, taken in order as they appeared, and represent as nearly as any series can, the average case of this disease. They are of children of between four and fifteen years of age, and with a disease of about two years and over. The measurements were taken of the femur, tibia, and foot of each side, as well as of the dimensions of the thigh and calf. The average shortening was found to be as follows: femur, 6.6 per cent. of its length; tibia, 5.4 per cent. of its length; feet, 5.0 per cent. of its length. Thus that in the femur is a fraction greater than that in the tibia, and when we consider the rate of growth, it will be seen that the amount of this loss in growth is almost, if not quite equal, since the natural increase by growth of the femur is the greatest occurring in the body. Comparing it with that in the rest of the limb, we find that of the femur is nearly sevenfold, tibia is nearly four and one-half fold, foot about threefold in length. Before the third year the length of the lower extremity is doubled, quadrupled before puberty, and increased fivefold by maturity. This difference in loss by growth, then, is seen to be in the same relation as the rapidity of growth. Thus the greater loss in the femur is in proportion to its greater normal development, and compared with that in the other parts of the limb, makes the whole nearly if not quite equal.

Turning to the soft parts, the observations were

made by measurements of the thigh and calf at the same points. It was found that the loss in the thigh amounted to one per cent. of the volume, as determined by this method, and in the calf, of .89 per cent. This very close resemblance scarcely needs comment other than calling attention to it.

The results of these measurements, showing as they do a uniform distribution of the loss of growth, point to the one conclusion, that it is the result of the lack of use, which is occasioned by the necessary fixation of the limb. To show that there is a relation between the amount of this shortening and the degree of confinement of the limb, I have grouped a number of cases which were treated by the Thomas splint. They were under treatment for practically the same length of time, and were in average of the same class of cases as in the preceding, but represent such during a period when the use of the limb was very strictly prohibited. The difference in length varied between one and one-half and four and one-half inches, with an average of 7.3 per cent. of the length of the sound limb. The volume of the thigh showed a loss of 23 per cent. and the calf of 17 per cent. of the sound limb.

Our facts are then the following: In all joint diseases there is a muscular atrophy occurring early in the disease, and persisting throughout its course.

The degree of this is not in proportion to the severity of the disease or to its duration, but it is determined chiefly by the amount of use permitted or possible to the limb.

This same atrophy occurs under other conditions, which restrict the use of the limb, but not occasioned by disease.

The atrophy is of the whole leg, being nearly uniformly distributed.

During the period of growth, the loss of development extends to the whole leg, and bears a relation to the degree of its confinement.

And from these facts the following conclusions are drawn: that the influence of the disease itself on the occurrence of this atrophy and impaired development is slight, but it is the result of the lack of nutrition,—a physiological result of the impaired use of the limb, which in the early stages is the result of the restriction, of either the voluntary or the involuntary action, showing itself in the general muscular wasting, and later in the loss of development, from the enforced rest, and which is seen in the smaller size of the whole limb.

The bearing of this on the treatment of chronic joint disease is evidently important. Perfect fixation, as nearly as possible, is essential during certain periods in the course of the disease, but during a large portion, movement and some use of the muscles is without harm, and this is particularly true of the long period of convalescence, when the activity of the disease has subsided, but actual use of the limb is not permissible. If during this stage we can allow, without harm, sufficient motion to the leg to stimulate some physiological nutrition, and supplement this by artificial stimulus, as by bathing, massage and electricity, we can obviate to a great extent this loss of growth which impairs the usefulness of the limb in these cured cases.

A LARGE MICROSCOPE is now being made in Munich for exhibition at the World's Fair in Chicago. It will magnify sixteen thousand times, and cost about six thousand dollars.

## NEW HOSPITAL CONSTRUCTION FOR THE PUBLIC INSTITUTIONS OF BOSTON.

BY OTIS K. NEWELL, M.D.,  
*Commissioner of Public Institutions, Boston.*

THE present year of the municipal government of Boston has been an important one in its relation to the care of the sick of our city and the opportunities here for the clinical study of disease, as there have been started two new sets of hospital construction from the plans of Mr. E. M. Wheelwright, City Architect. This work is especially important because, if Mayor Matthews's plans in supporting the views of the Commissioners are carried out, these buildings will be but the type of construction for others which are to follow. This will eventually centre and make accessible here in the city a vast amount of clinical material furnished by patients now scattered about in various parts of the city and State. Patients among the sick poor and insane will then (which is of first importance) be better cared for, be easily accessible to their friends, and at the same time furnish a great addition to the present opportunities in our city for the study and advancement of medical science.

There are now in charge of the Commissioners of Public Institutions of Boston 348 sick (poor and others) in hospitals, and 1,125 insane in various asylums. Among the insane, 750 odd are now boarded in various of the State institutions. This, of course, makes it hard and expensive for their friends to visit them, and deprives them in great measure of what benefit such visits are. The dormitory at Austin Farm, the second of the structures to be described below, is one of the additions to our hospital accommodations for the insane which, if followed, as is the proposal, by similar ones, will do away with this evil.

I shall give nothing further in the present communication than the descriptions of the construction of the two hospital buildings, as they have been kindly furnished to me by the City Architect.

"The cottage hospital on Long Island, Boston Harbor, is a building 211 feet long by 136 feet wide, with an interior court, and this is about half of the original plan. The rest of the building will be finished as soon as the demands require it.

"The main or administrative building is three stories high, with a 'hipped' single roof, and contains twenty-two rooms for the use of the physicians, nurses and matrons. The building is connected by a corridor 86 feet long to a two-story 'shed' house, and used for a diet kitchen, linen-room, and the care of attendants' rooms. Out from this building opens the ward 151 feet by 35 feet, and with ample accommodation for 100 beds. This room is heated by three large

stacks in different parts of the room, the registers placed near the top of the room, and ventilated by separate ventilating registers under each bed, which connect with one main duct carried to a hot exhausting-flue. At the end of the ward is a wing used for baths, and a large 'sun' room.

"The exterior of the hospital will be of cement and wooden 'styles and rails,' giving the appearance of the English old 'open-timber' construction. The exterior walls of the first floor of the administrative building and corridor are built of vertical two-inch and three-inch splined and grooved plank, plastered both on the outside and inside, the laths being nailed to a thin, three-eighths inch furring, and Portland cement used for the outside finish. This makes a practically fireproof construction for wooden buildings, as the walls have no channels for the passage of fire from one floor to another, and are also free from mice or vermin. The exterior walls of the ward-room are made of bricks of terra-cotta, from the sill to the plate, in which the plastering is applied directly, without the use of laths or furring. This 'terra-cotta lumber' is made in hollow blocks, so that the inside of the wall will not condense the moisture, but will be dry at all times.

"The whole of the first floor is of 'mill construction'; which means that large hard-pine timbers (10 by 14 inches), spaced about ten feet apart are used, and these are covered with a hard-pine under-floor three inches thick, so that it would take many hours for a fire to burn through to the basement. The basement does not extend under the ward-room, but the exterior walls are of piers with open screen between, giving a constant change of air there. Shutters are to be used in winter to close in between the piers.

"The central-ward building gives four separate wards for better classification and isolation of patients, and will have about 112 beds. The cost of this building, embodying that of the central ward will not exceed \$380 per bed. This price will include heating, ventilation and plumbing.

"The dormitory at Austin Farm is a building 153 feet long and 36 feet wide, with a wing 45 feet by 31 feet. The basement is used for boiler- and coal-rooms, workshops, smoking-room and large toilet-room, and is thoroughly well lighted. The first floor is divided into a dry-room (35 feet by 38 feet), a reception-room (19 feet by 33 feet), a dining-room (18 feet by 71 feet), and seven attendants' rooms, and one attendants' dormitory. The kitchen, a room 24 feet by 31 feet, is situated at the extreme end of the wing, and is ventilated by a large, brick ventilation-stack, and is well provided with closets. The second floor of the main building is one large dormitory containing 100 beds, and provided with attendants' and watchers' rooms; while in the wing are all the toilet- and bath-rooms, and small rooms for the sick patients. The building is finished throughout in express; and all the woodwork is of the plainest, having no deep mouldings or ledges for the accumulation of dust.

"The exterior of the building is to be of cement on wire laths, and divided into panels, as seen in the old English 'open-timber' work, with a pitch roof covered with cypress shingles.

"The first story is constructed of three by four inch

planks, standing upright, side by side, splined and grooved, and capped with a grooved hard-pine plate on which rest the second-floor timbers. The second story is constructed according to the customary method of frame buildings. On the outside and inside of this plank wall are nailed the three-eighths-inch furring strips, and on these the laths for the plaster, which will be of lime for inside work and of cement

for the outside. By this method of construction, the exterior walls have no passages or flues from the first to the second floor, for vermin or fire, as they are practically solid walls, and will also prevent all the cold winds of winter from getting through, thereby assuring a warm building.

"The cost of this building will but little exceed \$300 per bed."

DORMITORY, AUSTIN FARM

SOME GYNECOLOGICAL CASES AT THE BOSTON CITY HOSPITAL.<sup>1</sup>

BY J. G. BLAKE, M.D.

IN these days of frequent and successful capital operations in gynecology, it seems almost profitless to occupy the time of this Society with a recital of cases of minor importance, and without special scientific value. Nevertheless, as we cannot always control the conditions under which we find ourselves placed in regard to the character of our work, we can only do our best with the material at our disposal, and report the result. Perhaps some slight benefit may accrue in the way of information and encouragement to others not more favorably situated.

The Medical Department of the City Hospital is divided into three services — partly for the convenience of the staff, partly to suit their preferences as to the class of disease they desire to treat. The first and second services take their proportion of the general medical cases admitted, and equal shares of all the uterine cases (except laparotomies); while the third service, takes in addition to its portion of general diseases, all those of the nervous system. Ovarian cases, entered for operation, and any requiring laparotomy, are admitted only to the surgical wards.

This explanation is necessary in order to account for the absence from this paper of capital operations, such as ovariectomies, laparotomies for the removal of diseased tubes, and hysterectomies. The reader, and some of his colleagues, hope, that in the course of time, the propriety of establishing a complete and separate division as an adjunct to the medical department, will be recognized.

For the past year and a half, I have had charge of the uterine ward for a period of four months at one time, and eight at another. During this time of service, two hundred and fifty cases of uterine disease were treated, and of this number the following are among those of most interest: Fibroids, four; Alexander, ten; hamatocoele, four; pelvic abscess, six; puerperal septicaemia, ten; lacerated cervix, twenty; cancer of uterus, seven; cancer of vagina, two; lacerated perineum, ten; lacerated perineum and cervix, nine; stenosis of cervix, five.

To-night we will allude briefly to the Alexander's, septicaemias, and uterine fibroids — leaving the others for future discussion.

## ALEXANDER'S OPERATION.

The cases of Alexander's operation, ten in number (eight in the City Hospital, and two done at St. Elizabeth's), represent fairly the difficulties, the uncertain results, and the good results attending it. As the subject has never been formally brought before the Society, this record may serve as a text for discussing it.

My own mind is pretty well made up as to its value in a certain class of cases. It is hardly necessary to go into a detail of technique before you. It may be well, however, to point out to beginners, that it is by no means so easy of successful performance as many authorities would have us believe. Indeed, one of the chief reasons signed by some writers for discarding it, is the difficulty, uncertainty, and amount of time required to find the ligament. Three-quarters of an hour is said to be the average, but my experience leads me to believe it should be rather more than less.

That the ligament can be always found I do not believe. Sometimes it is rudimentary, and not to be distinguished; at other times it is entirely absent. I have seen three of the most skillful operators fail to find it. In two of these cases there was failure to find either ligament; in the other it was concluded that it was either wholly absent or so small as to be unrecognizable on one side, and no attempt was made to discover it on the other. In some it was found after tedious effort; in others it was located quite readily.

With the exception of a single ligament which was taken up in the inguinal canal (canal of Knuck), the operation was performed at the external inguinal ring with the spine of the pubis for guide. A blunt hook was used to lift up the fat, the muscular and cellular tissue, and the extremity of the ligament, which is not especially tendinous at this point. An advantage claimed in favor of operation at this point is less liability to hernia. On the other hand, it is alleged, and justly, that in the majority of instances the search for the ligament is shorter if the opening is made into the canal midway between the external and internal ring. Its tendinous character is better marked here; an incision of smaller size is sufficient; and anaesthesia is not necessarily required for the operation.

Some of our members will recall an occasion when a very expert and experienced operator spent forty minutes in finding the ligament on one side, while a few moments sufficed on the other. A similar experience happened to a friend and myself in one of my earlier cases, when having wasted a great deal of time in searching for it in the external ring, the canal was opened at the other side and it was discovered without difficulty. Some writers advocate the opening of the canal through its entire length, for the purpose of facilitating the operation; but the objection to this would lie in the increased danger of hernia. This might be avoided, however, by taking special care, and closing the wound immediately by deep sutures.

On the whole, I should incline to the external ring as safest for the patient eventually. It should not be forgotten that the prolonged narcosis — often extending to an hour and a half — is not wholly free from danger. One of these cases sank into a state of utter collapse, from which only the most vigorous methods steadily persevered in for a long period, succeeded in restoring her. In two instances I felt satisfied that the safety of the patient would be best promoted by operating only on one ligament at a time, letting the other rest for a few days or a week. While this may not seem good practice, it appeared the safest and wisest course to pursue.

The class of cases were the simple backward displacements so commonly found where instruments do not readily keep the uterus in position, or where they cannot be worn without inducing pain or distress. In all these the result has been, with one exception, uniformly good.

One case particularly calls for special notice. A woman, practically bed-ridden, morbid in mind, feeling that she was the victim of incurable spinal disease, with pain in the back, inability to walk, etc., was transferred to the uterine from the nervous ward. An extremely tender, retroflected, and enlarged uterus was returned to its normal size and position, by a month of glycerine-tampon-packing treatment; and then kept there by shortening each round ligament two inches

<sup>1</sup> Read before the Obstetrical Society of Boston, October 10, 1891.

and a half. The patient left the hospital free from backache, able to walk, strong, fat and happy. Such a result makes the physician's heart rejoice and leads him to believe that life is indeed worth living.

I have had no experience with cases where adhesions exist and have to be broken up, or with the many other complicated conditions which call for the operation. The future, I hope, will enable me to test its value more fully, and I shall be glad to report results. So far I have been more than pleased.

## Clinical Department.

### TWO CASES OF POST-PARTUM HÆMORRHAGE WITH SPECIAL FEATURES.<sup>1</sup>

BY S. L. ABBOT, M.D.

**CASE I.** Mrs. —, *quartipara*, over forty years of age. Called to this patient at five p. m. I found her in the first stage of labor. A male child was born at eleven p. m. Nothing abnormal in the labor. Following the birth of the child was a pretty free discharge of coagula. The uterus contracted peculiarly after the delivery of the placenta, becoming flattened from before backwards, extending somewhat higher than usual, and of abnormal width, with two deep, longitudinal grooves; the grooves and the ridge between them being each more than a finger's width in breadth. The organ was firm to the touch, but of this unusual shape. It was carefully watched for some time for fear it might become relaxed and hæmorrhage follow. A moderate dose of fluid extract of ergot was also given. This, however, caused so much pain that it became necessary to administer morphine to relieve it.

During the birth there was a laceration of the perineum which extended pretty deeply into the vaginal sphincter. This was closed by one deep stitch which brought the raw surfaces firmly together, so that they healed by first intention. In two of the previous three labors it had been necessary to sew up similar lacerations. The result of the stitching on the present occasion was to narrow the vaginal outlet pretty closely, partly from the fact that the vagina was rather small, the woman being somewhat under size.

On account of the unusual condition of the uterus I remained four hours with the patient watching for possible relaxation and consequent hæmorrhage. At the end of this time, as no change had taken place, I left her.

On the following morning the condition was the same. There had been no marked hæmorrhage.

At two o'clock of the following morning I was hastily summoned with the announcement that the patient was flowing freely. On reaching the house I was told that the flowing had ceased, but a considerable amount of clots had come away. On making a vaginal examination it was found that the vagina was distended to the utmost with coagulum. After this was removed the os uteri was found to be open widely, easily admitting the ends of four fingers and quite lax. No coagulum was in the lower part of the organ. Above the pubes it was felt to be flattened, grooved and contracted as before. There was no subsequent hæmorrhage. What was the probable explanation of the phenomenon?

It seems probably to have been caused by the damming up of the vaginal outlet by the suture. The flow from the uterus was not urgent and a small clot forming above the tampon which was placed within the sphincter vaginae during the insertion of the stitch, but which was subsequently removed, was probably obstacle enough to prevent a free escape of the flow from the womb, so that in time the stretched vagina above was fully distended, the clot backing up into the uterus itself. This probably excited contraction and emptying of the organ, leading to an abrupt escape of a good deal of coagulum, creating the alarm which led to my summons to the house. After the coagulum left in the vagina was cleared out there was no subsequent hæmorrhage. The uterus gradually contracted to its normal size, retaining as long as it could be felt its abnormal shape.

It should be remarked that there was no factor about the coagulum, and it was not thought necessary to wash out the vagina after its removal. Convalescence was rather slow, the patient suffering a good deal from left temporal neuralgia which was followed at the end of the third week by phlebitis below the right knee. There was no reason whatever to believe this was due to a septic cause.

**CASE II.** Mrs. G., *secundipara*. A young lady of marked nervous temperament, about twenty-five years old. When I reached the patient labor was well advanced, and a male child was born an hour after. The child was followed by a rush of blood, coagula and liquor amni, saturating six sheets folded many times beneath her, and extending from her heels to her neck on the India-rubber cloth below. The patient was blanched, but did not become unconscious from the flow. A mass of coagula and blood with liquor amni, scooped up with the hands, half filled a large chamber pot. The pulse was extremely weak, and the patient's condition called for prompt action to prevent, if possible, any further hæmorrhage. A half-drachm dose of fluid extract of ergot was therefore given at once, and stimulants were freely administered. The uterus was firm to the touch, and the hand was kept over it with the view of aiding the delivery of the placenta. This, however, was delayed. There were uterine pains, but the placenta was not expelled. The cord was kept tense with the right hand, and with the forefinger the fetal surface of the organ could be felt bulging into the vagina, but not advancing. There was, however, at that time no bleeding.

After waiting a reasonable time, having made my hand and arm aseptic with solution of the bichloride, I passed my hand without difficulty into the uterus to the fundus. The surface from which the placenta had been detached, was distinctly felt on the right side of the organ, and there was no hæmorrhage from it. At the fundus the afterbirth was felt to be held at that point, by a firm grip on its edge. A part of the organ extending from two to three inches from the edge was thus grasped. My first impression was that there must be an adhesion at this point; but in passing the tips of two fingers between it and the womb, with some difficulty, it was found to be held in place merely by the contraction of that organ. After scooping it from its hold, the placenta was easily removed and there was no more hæmorrhage.

In her first labor the patient was so suddenly taken with pains that there was not time to summon me, and a neighboring physician was called in. In this

<sup>1</sup> Read before the Obstetrical Society of Boston, October 10, 1891.

case also, the birth of the child was followed immediately by a very profuse hæmorrhage, so that, according to the patient's statement, she was unconscious for six hours.

### A DISPLACED APPENDIX CÆCI GIVING RISE TO SYMPTOMS SUPPOSED TO BE DUE TO AN OVARIAN TUMOR.

BY FRANCIS B. HARRINGTON, M.D.,

*Surgeon to Out-Patients at the Massachusetts General Hospital; Assistant in Clinical Surgery, Harvard University, Medical Department.*

Mrs. C., thirty-nine years of age, is the mother of two children, one five years old, the other, two and a half. She had always been well until six years ago, when a year before the birth of the first child, she began to have attacks of pain low down in the abdomen. These attacks occurred at intervals, and between them there were periods of comparatively good health. The pain was often intense, and sometimes accompanied by nausea, vomiting and abdominal distension. The attacks gradually diminished in frequency. Since the birth of the second child the attacks have increased in frequency and in severity. She has had for the last two years almost complete disability. There is constant pain in the pelvic region, backache, bearing-down feelings, with repeated attacks of abdominal colic, tenderness and distension. The patient had not consulted a physician since the birth of her child, although in a very wretched condition.

On vaginal examination, I found a somewhat irregular mass, the size of an orange, behind the uterus. It was not painful on pressure. The uterus was freely movable. There was no rise of temperature, the digestive organs were in good condition. The diagnosis of a cystic tumor was made and an operation advised. After opening the abdominal cavity, a tumor of the right ovary was found, and was removed in the usual way. The left ovary with the tube was also removed because it was enlarged and looked diseased. On examining the pelvic cavity, it was seen that the appendix cæci was lying out of its usual position and extended down along the posterior wall of the pelvis on the right side. It was somewhat thickened, reddened and rigid. It was abnormally hard to the touch. It was deemed wise to remove it. The patient made good recovery, and twelve weeks after the operation is about, free from the old pain and discomfort.

The following is Dr. W. F. Whitney's report of the appearances of the specimens:

"(1) One ovary was of ovoid shape, four centimetres by two centimetres and was attached at one end. The surface was slightly roughened. On section, numerous small cysts (largest one a centimetre in diameter) were disclosed, filled with a pale, watery fluid. Microscopic examination failed to show any marked deviation from the normal structure. The tube was of normal size, but slightly convoluted, the twists bound together by firm adhesions.

"(2) The other ovary was replaced by a single cyst about six centimetres in diameter. The walls were of moderate thickness, dense, with a few irregular thickenings. The inner surface was smooth, the outer slightly rough. Microscopic examination showed the wall to be made up of a dense fibrous tissue, — the outer part cellular, recalling the stroma of an ovary; in the inner part filled with thick vessels similar to

those of the centre of the ovary. In the wall was a minute cavity lined with low epithelium. The tube was slightly thickened on the peritoneal surface.

"(3) The appendix was slightly thickened especially at the apex which contained a small concretion. The peritoneal surface was thickened, and showed an increased vascularity, with here and there minute clumps of blood pigment. Nothing else abnormal noticed.

"The essential changes are a cystoma of one ovary, retention cysts of the other.

"Chronic peritonitis of the appendix, with a concretion present."

It is probable that much of the pain and discomfort arose from the condition of the appendix, and that the ovaries took only a minor part in causing the disability of the patient. Dr. Whitney has suggested that the pain which patients with chronic inflammation of the appendix suffer, may be caused in part by peristaltic action in that organ. Such an appendix could not be detected by manual examination.

The case suggests the importance of bearing in mind the possibility of a displaced appendix as a cause of pelvic disease in women, and the writer would urge the importance of examining the appendix in all cases of laparotomy in which it can be done with ease. I have seen several of these appendices in which the pathological changes do not seem to be commensurate with the symptoms. Yet their removal has relieved the patient of very great suffering.

## Medical Progress.

### RECENT PROGRESS IN THORACIC DISEASE.

BY GEORGE G. SEARS, M.D.

#### A VISIBLE HEART.<sup>1</sup>

The case is reported of a child, about a fortnight old, in whom the sternum and costal cartilages were imperfectly developed. The heart could be seen most distinctly through the thin cutaneous wall of the chest. The shape and size of the auricles and ventricles, with the filling of the auricles with blood, were quite as visible for practical purposes as if the organ were completely exposed to view.

#### CARDIAC TONICS.<sup>2</sup>

In a very instructive lecture on the cardiac tonics, G. Sée arrives at the following conclusions:

Digitalin increases the diastolic elasticity of the heart, thus increasing its capacity and allowing more complete filling of the arteries. The systole is not exaggerated, and the vessels are not always contracted, so that digitalin regulates the action of the heart without strengthening the organ. It is best given, if a large dose (half a milligramme, one-seventy-fifth of a grain) be indicated, twice on the first day, followed in the following two or three days by small doses to sustain the effect. Even then one is often obliged to wait before the desired result is obtained, as the drug is but slightly soluble, and owing to the feeble condition of the patient absorption may be slow.

Iodide of potash acts similarly; it dilates the vessels still more, and considerably facilitates the peripheral circulation as well as that in the nutrient vessels of

<sup>1</sup> New York Medical Record, February 11, 1891.

<sup>2</sup> Médecine Moderne, July 2, 1891.

<sup>3</sup> Read before the Obstetrical Society of Boston, October 10, 1891.

the heart. From the latter point of view it is a cardiac nutrient; from the former, it regulates its action, especially if there be pulmonary congestion, dyspnoea or asthma. One gramme (fifteen grains), should be given in milk or beer three times a day with meals for five days out of seven, and indefinitely continued.

Strophanthin is an energetic vaso-constrictor; it increases the force of the heart only indirectly, and its effect is transitory. It acts promptly and does not accumulate, one-fourth of a milligramme should be prescribed, either in tincture or pill form.

Sparteïn and convallamarin are often indispensable auxiliaries of the preceding drugs. The action of the first is almost instantaneous, but its effect is soon lost, so that it should be given two or three times daily; two to four grains may be given in twenty-four hours. Convallamarin has no cumulative action, and five to eight grains may be given daily.

Caffeïn is especially valuable as a diuretic in dropsy of cardiac origin; it is also a general excitant, but not especially of the heart.

Lactose, like caffeïn, is a renal diuretic and has no action on the heart or vessels.

#### PAINFUL SENSATIONS IN HEART DISEASE.

Nothnagel<sup>8</sup> has analyzed 483 cases of valvular cardiac disease with reference to the sensation of pain. Of 114 cases of aortic insufficiency it was present as a symptom in 69; of five cases of aortic stenosis it was present in two; of 23 cases of double aortic lesion it appeared in 15. Out of 17 cases of combined mitral and aortic insufficiency but three complained of it, and only 14 of a total of 183 cases of pure mitral insufficiency. In mitral stenosis it was present in four of 22 cases, and in double mitral lesions in 20 out of 118. It was not present in one case of pulmonary stenosis. It was therefore most common in combined stenosis and insufficiency of the aortic valves, most rare in pure mitral insufficiency, results which tally well with those of other authors; but it is to be said that Nothnagel includes all painful sensations, and not simply those of so-called steno-cardiac attacks, which practically occur only with insufficiency and stenosis of the aortic valve. Apart from the steno-cardiac paroxysms, of which shooting pain into the left arm is typical, other forms of pain are present in valvular disease, which have been variously described as burning, boring, tearing, etc. In this class of cases frequently, but not always, objective disturbances of sensation are found in an increased susceptibility to pain on pinching or pricking, in the precordial region, sometimes even extending around to the back. This hyperalgesia may also be present when the patient has no sensation of pain. In myocardial affections, where physical examination, as well as the history, is so often unsatisfactory, such painful sensations may direct one's attention to the heart or establish a doubtful diagnosis. Of course the mere fact of pain in the cardiac region does not point necessarily to a myocardial disease, for it is often enough present without; but the frequency of its presence in such affections would lead to closer examination before assuming it to be due to rheumatism, costal neuralgia, circumscribed pleurisy or the like. As regards the source of such pain in myocardial disease, it is possible that the cardiac ganglia whose sympathetic character has been demonstrated by His and Romberg are implicated. In valvular dis-

ease, however, from the greater frequency with which aortic lesions are accompanied by pain, it is probable that it originates in the vessels rather than the heart. The frequency with which aortic aneurism is accompanied by pain corroborates this view.

#### PURULENT PERICARDITIS TREATED BY FREE INCISION.

Davidson<sup>4</sup> reports the following successful case. The patient, a boy six years and nine months old, was admitted to the hospital suffering from empyema of the left side, which was treated by free incision. Twelve days later, signs of pericardial effusion having appeared, the pericardium was aspirated in the fourth interspace one inch from the left border of the sternum and pus drawn out. An incision was then made at the point of puncture, and a moderate sized drainage-tube inserted. Two months later the boy was discharged well, and has since remained in excellent health. Bronner<sup>5</sup> also reports a case in a girl aged eleven, which was treated in the same way, but death followed about four weeks later. The incision was made in the fourth intercostal interspace one inch to the left of the sternum, a trocar having first been introduced as a guide, and "the heart never seemed to come near either the trocar or the scalpel."

In commenting on Dr. Bronner's case, West<sup>6</sup> says that, in his opinion, the dangers of surgical interference with the pericardium are greatly exaggerated. The only risk is that of wounding the heart, and with care this may be avoided. Exploratory punctures and paracentesis he considered to be much more dangerous than incision, especially if the ordinary blunt aspirating needles are used. He has tapped the pericardium several times without any misadventure, though on one occasion he was alarmed by getting nothing but a jet of blood. He at once removed the needle, and of course drew off no fluid; but for some reason or other the patient was greatly relieved and rapidly improved from the time of the puncture. The chief risk is from error in diagnosis, as the difficulties in some cases are considerable in distinguishing between a greatly distended heart and pericardial effusion. Even then it is not a clean puncture through the walls of the heart which is dangerous, for this has frequently occurred as the result of accident and has even been deliberately performed with the object of tapping a greatly distended cavity. The fatal result has been due not to clean puncture but to laceration. With proper care, puncture of the pericardium may be performed without any real risk, and the dangers of the rapid removal of fluid are for the most part imaginary. The same may be said of washing out the pericardial cavity.

In conclusion, he states that the patient he operated upon has been for years in active work and is capable of any ordinary muscular exertion. Except for the scar there is absolutely nothing to indicate that he ever had anything the matter with him.

#### THE DIAGNOSIS OF LARGE PLEUROMY CAVITIES.<sup>7</sup>

Schultze reports a case which shows how difficult it may be to diagnose with any certainty the presence of a large excavation in the lungs. The most marked and typical signs of a cavity were found, yet at the autopsy no large cavity was found but only a system

<sup>4</sup> British Medical Journal, March 14, 1891.

of small spaces. The pleura was not adherent. The case was not of tubercular origin, and in case operation had been attempted as proposed, no brilliant result was likely to follow.

#### SALICYLATE OF SODA IN SEROUS PLEURISY.<sup>8</sup>

In 1877, Professor Germain Séé pointed out that in cases of articular rheumatism, salicylate of soda, while curing the primary disease, distinctly prevented inflammation of serous membranes. In 1883, Professor Aufrecht showed that the salicylate is an excellent remedy for idiopathic serous pleuritis, whatever their origin; this was subsequently confirmed by Professors H. Eichhorst, Maragliano and Stiller, and Drs. Drzewiecki, Tetz of Lublin (*Therapeutische Monatshefte*, No. 7, 1890), Déri (*Pester med.-chirurg. Presse*, No. 26, 1891), and Talamon (*Médecine Moderne*, No. 25, 1891). According to Tetz and Talamon, the curative effect of salicylate of soda in serous pleuritis is not less specific than in rheumatism. Dr. M. A. Strizover, of Odessa, now reports (*Médecinskoï Obzrenië*, No. 15, 1891, p. 218) eight cases of exudative pleurisy, in which he gave the drug internally, in one-gramme doses, three times a day. To prevent collapse the salicylate was always given after meals, each dose being followed by a draught of good wine. In seven cases temperature rapidly fell to normal, and the subjective condition improved, while in about a week dyspnoea was relieved and the area of dullness lessened, every one of the patients completely recovering in about eighteen days. In the eighth case the treatment (of four days' duration) utterly failed. The symptoms pointed to empyema. An exploratory aspiration was made, and a sero-purulent fluid escaped. The patient was ultimately cured by a radical operation (excision of rib, etc.). Dr. Strizover comes to the following conclusions: (1) salicylate of soda is undoubtedly a most valuable remedy in serous pleuritis; (2) at the same time it affords a reliable means of determining the character of pleural effusion, that is, of differentiating serous from sero-purulent or purulent pleurisy.

#### ACUTE PULMONARY CONGESTION OF A PSEUDO-PLEURITIC TYPE.

Dr. Berthier<sup>9</sup> says that there is a form of pneumonia, termed by Professor Grancher *pneumonie massive*, which gives the signs of pleural effusion, namely, complete dullness on percussion and absence of vocal vibrations and respiratory sounds. The ramifications of the bronchial tubes up to the larger divisions are filled with exudation. Grancher has also described another form which yields similar physical signs and which he has named *spléno-pneumonie*. He supposed it to be due to a sero-albuminous and epithelial inflammation. Dr. Berthier reports a case occurring in a young man after influenza. There were signs of fluid at the left base, but exploration with the needle was negative. The expectoration consisted at first of pure blood. On the fourth day the patient grew much worse and became cyanotic, and similar signs were found at the right base with bronchial breathing and bronchophony at the angle of the scapula. Later, friction sounds were heard over the sub-pinnous fossa, first on the right, and later on the left side. The patient was discharged well in six weeks' time. Berthier remarks that the "congestion" was very intense in this case, the paren-

chyma of the lungs as well as the smaller tubes being infiltrated with blood.

#### AUSCULTATORY PERCUSSION.<sup>10</sup>

From a pretty large number of observations on both the living subject and on the cadaver just previous to the autopsy, F. W. Jackson has reached the following conclusions as to the value of auscultatory percussion:

(1) It is of no value, in his hands at least, in the examination of the liver, kidneys or spleen.

(2) It is a very valuable method of estimating the area of cardiac dullness, and it is much superior to ordinary percussion for this purpose, but it is not to be regarded as absolutely accurate.

(3) It is doubtful if it can be relied upon to delineate less than a quarter of an inch enlargement of the heart, and therefore is of no value in hypertrophy of a heart without dilatation.

(4) By its use the heart may be outlined in conditions of the lung, such as emphysema and consolidation in which ordinary percussion is not available.

(5) If by its use the left border of the heart is recognized as being outside the areola of the left nipple, or, better, more than four inches and a half from the midsternal line in a man of medium size, or five inches in a large man, the heart may be considered to be enlarged, especially if the vertical diameter exceeds four inches.

#### THE TREATMENT OF ACUTE LOBAR PNEUMONIA.<sup>11</sup>

In a very interesting paper W. P. Fewick analyses 1,000 cases of pneumonia, and thus summarizes his results: Every item of evidence, whether pathological or clinical, leads to the inevitable conclusion that the fatal result of acute pneumonia is caused by cardiac failure, which is the result of two general factors, increased resistance to the propulsive action of the heart and a progressive deterioration of its muscular substance induced by the high temperature, for it has been shown in the body of the paper that death is most liable to occur at two periods of the disease, about the fifth day, when the fever is at its height, or at the crisis when cardiac failure is apt to result from its sudden withdrawal.

Two great methods of treatment were examined in detail as to their influence upon the mortality of the disease. In one we find the chief remedies were aimed at relieving the condition of the lung; and while stimulants were freely administered, with the object of whipping up the flagging heart, the causes of its physical lameness were allowed to go on unmolested. The result was that among 552 cases so treated the mortality exceeded 23 per cent., although alcohol was given in no less than 70 per cent.

In the second case, a method of treatment was adopted with one special object, to economize cardiac force by minimizing the injurious influences of fever. In 108 cases of similar severity to the foregoing the treatment consisted in the systematic reduction of temperature by sponging (the temperature of the water being 116°), or by ice cradling. Of this number only 15 (11 per cent.) received alcohol, and only 10 per cent. died. Again, among the former class 46 deaths resulted from collapse at the crisis of the fever. Among the latter, where especial attention was paid to this

<sup>8</sup> Supplement of British Medical Journal, October 21, 1891.

<sup>9</sup> Le Méd., New York Medical Record, September 12, 1891.

<sup>10</sup> New York Medical Journal, June 29, 1891.

<sup>11</sup> Lancet, January 31 and February 7, 1891.

source of danger, not a single death is reported from this cause. Nothing could be more conclusive, for these facts show to what a considerable extent the mortality from acute pneumonia may be reduced when prophylactic treatment is applied with a view of strengthening that vital position against which death concentrates the force of his attack. And this success which has attended this rational treatment of acute pneumonia appears as a still further argument in favor of the specific febrile nature of the disease, for it would indicate that the consolidation of the lung is, after all, but an analogue of the typhoid ulcer and of the scarlatinal sore throat—a characteristic result, but never the cause of the disease. It was also shown that, first, the quantity of albumen in the urine is of considerable prognostic value, secondly, that the crisis is often a period of great danger to life, and, thirdly, that those cases which begin with a severe gastro-intestinal attack are twice as liable to end fatally as those which begin with the more usual initial rigor.

#### RESECTION OF THE LUNG.<sup>12</sup>

Dr. Tuffier presented at a recent meeting of the Société de Chirurgie a patient on whom he practised in March last excision of the summit of the right lung for localized tuberculosis, and gave the details of the operation. The man, aged twenty-five, was of stout build and enjoyed perfect health until two months ago, when he was attacked with cough, night-sweats, and tuberculous laryngitis, and for which he entered the hospital. Auscultation revealed the following symptoms: At the top of the right lung slight dullness, respiration rude and jerky, expiration prolonged, and dry crepitation in coughing; the left lung was perfectly healthy, and the patient, being made aware of his condition, accepted the risks and perils of operative interference, especially as medical treatment but little changed his condition. The *modus operandi* was as follows: A cushion being placed under the back so as to efface as much as possible the subclavicular fossa, an incision was made through the second intercostal space to within half an inch of the sternum; the great pectoral and the intercostal muscles were similarly incised, and the pleura brought to view, which being cut in turn, the tissue of the lung appeared. The operator then passed in his finger and detached the serous membrane above and without with comparative ease, but when he reached the inside the membrane yielded, and immediately a hissing sound occurred, indicating an escape of air or the formation of a pneumothorax. The finger was applied to the spot, and subsequently a plug of iodoform gauze. Continuing the operation, M. Tuffier passed his finger behind the summit of the lung, and seizing the tissue with a special flat forceps drew it forward, threw a ligature around it and fixed the pedicle to the peritoneum on the internal side of the second rib. The muscles were then sutured and the wound dressed with iodoform. The piece resected was examined, and in its centre was discovered an induration of about the size of a small walnut, and surrounded with tubercles in which bacilli existed. The man made a rapid recovery, and a minute auscultation of the lung showed that the respiratory murmur, although it was a little weakened, was present throughout the whole organ without revealing the slightest sign of a pleural effusion.

## Reports of Societies.

### AMERICAN GYNECOLOGICAL SOCIETY.

SIXTEENTH ANNUAL MEETING HELD AT WASHINGTON, SEPT. 22-24, 1891.

(Continued from No. 23, page 606.)

Dr. CORNELIUS KOLLOCK, of Cheraw, S. C., read a paper on

#### THE IMMEDIATE CLOSURE OF LACERATION OF THE CERVIX.

The writer would not say that lacerations of the cervix should always be closed immediately, but he believed that there were many instances where it is not only proper but urgently demanded. Where the conditions are favorable, and it can be done without too much handling of the congested and torn cervix, the sooner the cervix is closed the better, not only for the instant relief afforded, but for the promise of a more sure and complete union of the parts; the woman is also saved much mental and physical suffering.

He believes in some respects the primary operation for laceration of the cervix stands to the secondary operation, as the primary operation for laceration of the perineum does to the secondary operation in cases of that kind. In both primary operations fresh parts are brought together, and healthy union is very sure to take place. The knife is not used in either case, and the patient is saved shock from that source, and also saved the loss of blood, which is sometimes considerable in the secondary operation on both cervix and perineum. The writer reported three cases of laceration in which he operated immediately after labor, with signal success.

It has been claimed that sutures introduced for the immediate closure of a laceration of the cervix cannot be depended upon, that as the congestion and tenderness of the cervix subsides they will become loose and fail to keep the edges of the laceration in proper coaptation. In answer to this, it may be said that it is not at all uncommon for sutures to pull out when the secondary operation is done for laceration of the cervix. The objection to the secondary operation is that the presence of cicatricial tissue renders the parts more difficult of coaptation, and the process of union is slower. The congestion and tender condition of the cervix does not so strongly forbid the introduction of sutures into it. In the Cesarean section, which is now done with signal success, compared to what it was twenty five years ago, sutures are introduced into the uterus when it is in the highest state of congestion, and when its vascularity is very great, and the tendency of the sutures to pull out, is not reckoned among the most patent causes of the failure of the operation.

Dr. CHARLES JEWETT remarked that this operation was frequently advocated but very little practised. He had done it in a few instances with entire satisfaction. It is a proper procedure where the cervix is torn to any extent, and where it is deeply torn it is imperative. The operation may be objectionable in ordinary hands, but presents no difficulties for the expert. There was danger of infection to the patient, and much manipulation of the passages after labor should be avoided. If the passages were thoroughly aseptic, he believed many of the minor lacerations would heal spontaneously.

DR. EMMET would not undertake to immediately repair a lacerated perineum unless there was hemorrhage. If you guard the patient against blood-poisoning, local peritonitis or cellulitis by keeping the cervix clean, it will repair itself. If the laceration be a deep or extensive one, he would repair it if possible.

DR. COE regarded the measure as a purely haemostatic one. He regarded a laceration of the cervix as a contused wound, which should be allowed to heal by granulation.

DR. A. P. DUDLEY was in favor of the primary operation, because it secured immediate union and saved the difficulty of cutting away any portion of the uterus to get union by the secondary operation, thus also avoiding the deformity resulting from the use of the knife.

DR. KOLLOCK, in closing the discussion, remarked that, without regard to the fact of hemorrhage being present, if the laceration was extensive, he would advocate its immediate closure.

DR. EUGENE GEHRUNG, of St. Louis, read a paper entitled,

#### THE PREVENTATIVE AND CONSERVATIVE TREATMENT OF PELVIC TUMORS.

In many instances of pelvic tumor surgical treatment is not applicable where other means of palliation are possible. Where the same or nearly the same result can be obtained by minor means, though less brilliant, they should have the preference. There is a universal law — the greater the resistance to an imprisoned force, the greater the tendency to break the barrier; and, *vice versa*, the barrier being broken, the less the tendency of the force to assert itself. This law is wonderfully illustrated in pelvic tumors — the greater the resistance the more rapid and destructive is their growth, and, *vice versa*, the lesser the resistance the lesser their growth; and in the absence of resistance their growth frequently comes to a stand-still, and at times becomes retrograde. The sudden springing into life and rapid growth of many small myomata which may have existed in the pelvis for years, is due to the tumor becoming compressed and irritated; the circulation being interfered with, congestion follows, and it grows rapidly. Resistance and growth go hand in hand. Many subperitoneal tumors commence to grow rapidly only after they begin to sink into the small pelvis, where the resistance is the greatest. The ovary is subject to the same law, the commencement of its abnormal growth frequently dating from its displacement or strangulation by adhesions. If displaced, it suffers pressure from the surrounding organs, and pathological processes follow, with the development of cysts.

The same is true of the uterus, which becomes enlarged it through displacement its venous circulation is interfered with, or atrophied if its arterial circulation is impeded. It may be stated, as a general rule, that either one of these three conditions — the incarcerated myomata and other tumors, the displaced ovary, or the strangulated womb — will, upon being released from their precarious positions, cease to grow, and if kept free from pressure, will in time return to their normal size.

As preventative measures, and as a means of obtaining these results, the writer recommended: (1) a clear and early diagnosis of the tumor; (2) the hands of the operator, by means of which possible adhesions

may be broken up and the tumor lifted out of the bony pelvis; (3) the almost lost art of the scientific use of the pessary — the tumor or organ being freed from its imprisonment should be supported in the right position by a pessary. Tampons of cotton or other material may be used as a temporary means, but as a rule, they are found inefficient. Three cases were mentioned as illustrative of each of these three conditions, where the writer was successful in arresting the growth of the tumors.

DR. GEHRUNG claimed that if these tumors were relieved from pressure and from interference with their circulation, that they would lose their energy if not their vitality.

DR. E. REYNOLDS, of Boston, read a paper on

#### THE ANATOMICAL RELATIONS OF THE LACERATED PERINEUM TO THE MECHANICS OF ITS CAUSATION.

The paper began with an account of some observations which the writer had been making during the last five years upon the shape and position of the rent in different cases, with an attempt to classify all perineal and vaginal tears as modifications to a greater or less extent of one type form, which is substantially that described by Dr. Emmet in 1883, consisting of two lateral longitudinal tears of the vagina, joined at their lower extremities by a transverse tear and connected with the external surface by a median tear of the tissues below the crescent. This tear, but slightly modified is stated to be the most common form. That which has seemed to be the next in frequency is one of the lateral tears, the half crescent, and the external tear. The crescent alone is not infrequent. I have also seen one lateral tear extend down through the skin by the side of the anus, without passing towards the median line. The writer thought that all lesser variations could be arranged under these four varieties. He then attempted to explain the determination of the rent by reference to the pelvic anatomy dividing the tissues of the pelvic floor into layers, of which the superior consists of the recto-vesical and obturator-vesical fascia, with the coccygeal muscles, reinforced anteriorly by the triangular ligament; while the inferior layer consists of the two layers of the superficial fascia, compressor urethrae, superficial, transverse and sphincter ani muscles.

In detail, he then explained the anatomy in its relation to the causation of the different rents referred to. He believed the essential element in the repair of all lacerations must consist of the insertion of such sutures as will draw the torn edge of the upper layer downward, and those of the lower layer upward, until they meet at the central point from which they were originally separated.

DR. GEORGE KEITH, of Brooklyn, read a paper on

#### THE ELECTRICAL TREATMENT OF UTERINE FIBROIDS IN ENGLAND.

A careful study of the work of the Keiths and other surgeons in Great Britain for some years past, and a comparison of the results obtained by the electrical treatment for the cure of uterine fibroids and the operation of hysterectomy and removal of the ovaries, confirmed his belief in favor of the electrical treatment. The treatment of these fibroids should not be restricted to any one method. The older Keith, the writer said, had by no means given up hysterectomy, having operated three times within the last six months to the

writer's knowledge, but he does believe electricity will cure the vast majority of cases, and guard against the necessity of hysterectomy in many. Hysterectomy is, no doubt, often performed for the removal of a tumor giving little trouble, which could have been cured by electricity.

Hysterectomy has in its favor, when the patient does not die after the operation, that the tumor is done with for all time, and the convalescence is rapid. The disadvantages are: the mortality, the melancholic condition into which patients frequently fall, the fact that the life of the ordinary fibroid is limited.

Electricity is in its infancy. When it is as old as hysterectomy, the death-rate will have been much diminished. There are some cases where operation is to be recommended. This must be insisted upon, for the opponents of electricity are apt to say that its advocates decline all operative procedures on all occasions. Hysterectomy is advisable in large fibrocystic tumors, and also perhaps in those surrounded by free fluid; also for removal of the appendages when the tubes and ovaries are seriously diseased, especially if there be any suppuration.

Dr. W. E. Ford recalled the question raised in the Society last year; as to whether there were any actual cures of fibroids by galvanism, and stated that since then he had investigated a number of the cases treated by him in the past seven years, and found that a large number of the small fibroids were cured, and the very large intra-mural growths lessened in size. In dangerous cases of large fibroids galvanism promises more than hysterectomy. These large fibroids are adherent and dangerous cases for operation, but they are safe ones for electricity provided there is no history of pus accumulation in the pelvis. The element of cure in the galvanic current is its amperage and not its voltage; the volume and not the tension produces the electrolysis.

Dr. SUTTON was strongly opposed to electricity in these cases, and believed that hysterectomy was the only rational procedure.

Dr. W. H. BAKER, of Boston, said electricity for the treatment of fibroids had been a success in his hands, and he was satisfied with the results in nineteen cases out of twenty.

Dr. CLEMENT CLEVELAND, of New York, read a short paper on the advantages of

#### LAPAROTOMY IN TRENDELEBURG'S POSTURE, WITH EXHIBITION OF A NEW OPERATING-TABLE.

This posture was first recommended by Professor Trendelenburg, of Bonn, in 1884, but has not been used until recently in this country, when Dr. Edelholz, in 1889, brought out his table adapted for laparotomy in this posture as well as for general gynecological work.

In this posture the body is so placed that the intestines will drop toward the diaphragm, and at the same time leave the abdominal muscles relaxed. The body is inclined with the head downward, the weight of the body resting on the shoulders, the thighs and knees flexed on the body so as to secure relaxation of the abdominal muscles. A saving in time of at least fifty per cent. is gained by the use of this posture in preference to the ordinary laparotomy position.

The writer exhibited the table which he had devised, which was a modification of the Edelholz table, and was alike useful for the Trendelenburg posture or for

general gynecological work. When used for the latter purpose, it was brought to a horizontal position and firmly clamped, and would sustain a weight of two hundred pounds.

Dr. HENRY D. FRY, of Washington, read a paper on

#### DIABETES MELLITUS GRAVIDARUM.

Gravidity increases the susceptibility of woman to certain diseases, and often changes the type of the malady by accentuating its dangers.

Pregnancy rarely occurs in diabetic woman, — the disease tending to produce a diminution of sexual energy. Diabetes undoubtedly occurs in women already pregnant, but is apt to escape notice in the majority of cases.

The urine should be examined for sugar where there are obscure symptoms in the pregnancy; also where there is a dead child born without apparent cause.

When there is a predisposition to diabetes, pregnancy is liable to act as an exciting cause. It may develop in the beginning of gestation or be deferred until about the period of quickening. Pregnancy sometimes causes the disease to assume an acute form. Pregnancy is frequently interrupted by miscarriage or premature birth of a dead child usually about seventh month. Excessive development of fetus has been observed. In some cases pregnancy will clear up the diabetes, which will not appear until a subsequent pregnancy. Cases recovering after labor should be carefully watched to prevent a relapse. The symptoms after labor in severe cases of diabetes, especially where the child is dead, are those of exhaustion and threatened collapse, mental condition blunted, death preceded by coma from few hours to several days.

*Prognosis.* — Mild cases become acute, and acute ones progress rapidly to a fatal termination. Some few cases remain mild, and extend through repeated pregnancies. Prognosis very grave, if a child is born dead prematurely; favorable, if born healthy at term.

The writer was of the opinion that a diabetic woman should not marry.

*Treatment.* — Induction of premature labor. In the mild cases interference is not justifiable. In the acute cases, with rapid emaciation and exhaustion, prompt action is demanded. The child usually succumbing about the seventh month, labor must, therefore, be induced at the earliest period of viability.

(To be continued.)

#### THE OBSTETRICAL SOCIETY OF BOSTON.

CHARLES W. TOWNSEND, M.D., SECRETARY.

MEETING of October 10, 1891.

Dr. BLAKE reported

#### SOME GYNECOLOGICAL CASES AT THE CITY HOSPITAL.<sup>1</sup>

Dr. ABBOT wished to speak of a method employed by him of introducing glycerine into the vagina. He used glycerine plasma, and thought the amount of glycerine which could be introduced in this way of great advantage. His mode of using it consisted in taking a common rubber syringe with fair-sized barrel, cutting off the end, then putting in the tampon, and on top of this the plasma, introducing into the vagina, and by the means of the piston injecting first plasma then tampon.

Dr. DAVENPORT said he had done the Alexander

<sup>1</sup> See page 622 of the Journal.

operation but twice, and thought that pessaries could be used in most cases of displacement; where they are not, there is apt to be tubal trouble. He had seen some cases where patients were worse after operation.

DR. HARRINGTON had never regretted doing the operation. He had seen slight hernia follow. He had broken one ligament, but found a large one on the other side which had held for six months. He sewed wound up without drainage.

DR. BLAKE thought the operation saved the woman from a life of bother and annoyance from a pessary.

DR. SINCLAIR: Is it necessary for a woman to wear a pessary for a life-time? The uterus held in position becomes lighter, and after a time, will remain in position if the supports below are intact.

DR. RICHARDSON thought the cases of septicæmia of particular interest, as showing what could be done with proper treatment, even at a late date. At the Boston Lying-in Hospital, cases were detected at once. Patients with an elevation of temperature which did not come down in the morning were immediately looked at, washed out with corrosive, and iodoform used; the temperature would fall at once.

DR. HARRINGTON reported

#### A CASE OF REMOVAL OF AN INFLAMED APPENDIX DURING OVIOTOMY.<sup>2</sup>

DR. DAVENPORT: I think it is a valuable suggestion in cases where pain has been present and unaccounted for.

DR. BLAKE: In cases of ordinary operation for pelvic trouble, would the reader advise searching for and examining the appendix, and should the wound be increased for this purpose?

DR. HARRINGTON: I think it a wise thing to look for the appendix without enlarging the wound.

DR. BLAKE: The ordinary incision is very small, and is not large enough to examine much of the pelvic contents.

DR. REYNOLDS: In the case reported, did the appendix lie in the pelvis?

DR. HARRINGTON: Yes.

DR. BLAKE: This point should certainly be borne in mind. I recollect one case which ended fatally where an abscess had ruptured.

DR. HARRINGTON: I think it well to look at the appendix in all cases where the amount of suffering is disproportionate to the apparent amount of disease.

DR. BAKER: This would make us more conservative.

DR. BLAKE: This accounts for pain following laparotomy where the cause had apparently been removed.

DR. SINCLAIR: Can the appendix be distinguished by vaginal examination?

DR. REYNOLDS spoke of a case where nothing was found, and yet, at operation a diseased appendix was removed.

DR. ABBOT reported

#### TWO CASES OF POST-PARTUM HÆMORRHAGE.<sup>3</sup>

DR. RICHARDSON: It is, I think, a great mistake to give ergot before the placenta has been removed, and also think it a very poor means of arresting hæmorrhage, as much blood can be lost before ergot begins to have any effect upon it. In Dr. Abbot's case I think it was the ergot which caused the contraction which held the placenta.

DR. ABBOT said that he had come to the same conclusion himself as to the cause of the retention of the placenta; but the urgency of the case was such that he wanted to get the womb well contracted at once, and so gave the ergot. He did not, as a rule, give it after the birth of the child, but only when the womb failed to contract well after the placenta had come away. He never gave it for the purpose of expelling that organ.

DR. REYNOLDS had a case of hæmatoma in the labia due to injury of vessel by Hagerdon's needles. Should never use a needle of this make to repair a perineum after labor.

DR. COTTING exhibited Needle-Holders.

DR. BROWN showed a Specimen of Fatty Placenta, from Dr. Forster.

### Recent Literature.

*Epidemic Influenza: Notes on its Origin and Method of Spread.* By RICHARD SISLEY, M.D., F.R.C.P. London and New York: Longmans, Green & Co. 1891.

This book is a royal octavo of 150 pages, very handsomely gotten up by the publishers. It is divided into fourteen chapters, with an appendix giving the text of the English Infectious Disease Notification Act of 1889, and an index.

The title would be still more correct if it read, *Epidemic Influenza: Notes on its Origin and to Prove its Spread by Contagion.*

The heading of Chapter V reads thus: "Influenza is contagious, and is chiefly, if not entirely, spread by contagion. Nature of the evidence offered in support of this view."

On page 88 the author states as a fact that, "influenza spreads along the most frequented lines of human communication." Chapter XIV is one page in length, and is a plea that influenza should be placed by a short act of Parliament "in the position to which it is justly entitled amongst the infectious diseases for which notification is compulsory."

The writer treats his subject from the standpoint of the advocate rather than from that of the judge. Every earnest contribution to the study of this perplexing malady is, however, worthy of serious attention, and especially so now that the disease has again manifested itself in a serious form at several points on the Continent of Europe.

*Influenza or Epidemic Catarrhal Fever.* An Historical Survey of Past Epidemics in Great Britain from 1510 to 1890. Being a new and revised edition of "Annals of Influenza," by Theophilus Thompson, M.D., F.R.C.P., F.R.S. By E. SYMES THOMPSON, M.D., F.R.C.P., etc. London: Percival & Co. 1890.

As indicated on the title-page this volume is a new and revised edition of the well-known treatise on Influenza published under the auspices of the Council of the Sydenham Society as one of the Society's series of publications. In addition to the revised text of his father's work, the present work, by Dr. E. Symes Thompson, contains seventy pages devoted to the epidemic of 1889-90, a summary of epidemics, and a chronological survey of recorded epidemics adapted from Hirsch.

<sup>1</sup> See page 141 of the Journal.

<sup>2</sup> See page 125 of the Journal.

The author's conclusions in regard to the question of contagion tally with those to be drawn from data obtained by the Massachusetts State Board of Health. His closing remarks seem to us so sensible and judicial that we quote them in full: "The greatest difference has prevailed, and still prevails, upon the apparently simple question of the contagiousness of influenza. A careful résumé of the evidence and opinions of competent observers, however, authorizes the belief that the disease is contagious, but it does not of course follow — nor does the author believe — that contagion is the only, or even the most frequent method of communication. The assertion that the malady had been imported into this country by direct contagion from parcels, letters, etc., emanating from infected districts, is not borne out by facts; at any rate, the history of the outbreak as it affected the post office and foreign office employees affords the idea no kind of support. The fact that the disease does not spread more rapidly now than of yore, in spite of the present methods of rapid transit, and the fact, too, that it does not necessarily spread along the main lines of travel, suffice to demonstrate the fallacy of the assumption of the disease being spread principally by contagion. Contagion, such as it is, seems to act more promptly on persons engaged in the open air, but there are so many apparent exceptions to this rule that it would be imprudent to insist upon it."

*Essentials of Physiology.* Arranged in the form of Questions and Answers. Prepared especially for students of medicine. By H. A. HARE, B.Sc., M.D. Third edition, thoroughly revised and enlarged; pp. xlvii, 193. Philadelphia: W. B. Saunders. 1891.

The enlargement of this edition consists of nine double plates, reproduced from Arnold's *Icones Nervorum Capitis*, to illustrate the anatomy of the cranial nerves. These plates are handsomely printed, and will be very welcome to many although their size renders them a little confusing on account of the wealth of detail. The "revision" of the question portion of the book can still be much improved, although this "compend" is even now better than many of the kind.

*Medical Symbolism in Connection with Historical Studies in the Arts of Healing and Hygiene.* No. 9 in the Physician's and Student's Ready Reference Series. By THOMAS L. SORINSKEY, M.D., Ph.D. Illustrated. Philadelphia and London: F. A. Davis. 1891.

The author of this essay, though born in Ireland, received his medical education and practised his profession in Philadelphia, where he died in his thirty-seventh year, shortly after the completion of this little treatise on a subject which deserves a more accurate knowledge than is probably possessed of it by most of the medical profession.

The book shows to what uses proximity to so excellent a medical library as that of the College of Physicians, of Philadelphia, may be put — a library which the author regards as "the centre, probably, of medical learning in the United States."

Æsculapius and the Æsculapian Serpent and Staff; Diiarra, a god of pestilence; Hygieia, the goddess of health; medical talismans and amulets; pharmacists' symbols; miscellaneous medical symbols and medical symbolism in practice, are the subjects of the principal chapters of the book.

*Fever: Its Pathology and Treatment by Antipyretics.* No. 10 in the Physician's and Student's Ready Reference Series. Being an essay which was awarded the Boylston Prize of Harvard University, July, 1890. By HOBART AMORY HARE, M.D., B.Sc., etc. Philadelphia and London: F. A. Davis. 1891.

The title of this essay, when presented to the Boylston Prize Committee, early in 1890, was, "The Uses and Value of Antipyretics." The essay is a concise summary of the conclusions of many of the best observers, by one who has had some personal, experimental and clinical experience in the subject treated. A record of the untoward effects produced by the various drugs considered is given in tabular form. There is, it seems to us, an undue tendency at present to neglect and decry the antipyretics. Some have failed to use them with discretion, and as a result, others fail to use them at all. Dr. Hare recognizes the value of the coal-tar products, both as antipyretics, when suitably employed, and as analgesics. He thinks that antipyrin stands foremost in the ranks of the antipyretics, with antifebrin next, while thallin and phenacetin follow, with perhaps (we should say certainly) a preference for the latter. As an analgesic, he still puts antipyrin in the lead, but regards phenacetin as quite as useful an analgesic as antifebrin and more safe. Thallin possesses hardly any such power. Dr. Hare's essay is a convenient and judicious summary of the subject treated.

*The Pathology, Diagnosis and Treatment of Intracranial Growths.* Fiske Fund Prize Dissertation. By PHILIP COOMBS KNAPP, A.M., M.D. (Harvard) Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System to Out-Patients, Boston City Hospital; Member of the American Neurological Association; Fellow of the Massachusetts Medical Society, etc. Boston: Press of Rockwell & Churchill. 1891.

Dr. Knapp's essay is based upon the records and autopsies of forty cases, of which thirty-eight were patients at the Boston City Hospital. The greater number of them had not previously been reported. The author has also availed himself freely of the literature of the subject without attempting an exhaustive review of it. His references are to sixty-two authors or subjects, and he draws his conclusions from 965 reported cases, including his own. The 161 pages of his book are marked by the thorough and painstaking work to which we are accustomed in the author, with a clearness of statement and excellence of diction and a systematic arrangement which make the subject interesting and the search for information as easy as it can be in the absence of an index. The essay is a valuable contribution to the literature of its subject.

*Memoir of Joseph Leidy, M.D., LL.D.* By HENRY C. CHAPMAN, M.D., Professor of Institutes of Medicine in the Jefferson Medical College. From the Proceedings of the Academy of Natural Sciences of Philadelphia, June 30, 1891.

This is a graceful and well-deserved tribute to the memory of a very remarkable man, the extent and accuracy of whose scientific learning was only equalled by the sweetness of whose character. Of his friend and teacher, Dr. Chapman says: "It falls to the lot of but few, living in the midst of a great community for threescore years and ten, to have never made an en-

emy during that long period, but to have gained universal affection, esteem and respect. Yet this may, in truth, be said of Leidy."

After two years' experience as a practitioner of medicine, Dr. Leidy gave up practice and devoted himself entirely to study and teaching — with what results, the love and admiration of his pupils, the list of his contributions to science embracing no less than 553 titles, and the names of the learned societies in all parts of the world to which he was elected a member, declare.

It is a curious and interesting fact, noted by Dr. Chapman, that the first scientific communication of any kind, made by Dr. Leidy, was a paper on the anatomy of *Littorina angulifera*, submitted July 16, 1845, to the Boston Society of Natural History, and published in that society's journal.

*Essentials of Nervous Diseases and Insanity.* By Joux C. SNOW, M.D. 12mo, pp. viii, 194. With forty-eight original illustrations. Philadelphia: W. B. Saunders. 1892.

On general principles we can find no reason for commending the various brief compends which are published by various houses. Their sole reason for existence seems to be the opportunity they afford a lazy student to cram up for examination. The volume before us, however, is clearly and intelligently written; we have noted few inaccuracies and several suggestive points; some affections unmentioned in many of the newer text-books, such as Morvan's disease and acromegaly are noted, although others, of equal importance, are omitted. Curiously enough, no mention is made of the so-called traumatic neuroses. In some sections brief bibliographies are given. In the section on sexual perversion, this bibliography fails to give the title of Krafft-Ebing's work, obviously an oversight, as Krafft-Ebing is directly quoted.

*The Practice of Hypnotic Suggestion.* By GEO. L. KINGSBURY, M.A., M.D. 8vo, pp. viii, 206. Bristol: John Wright & Co. 1891.

The aim of the present work, which grew out of the discussion of hypnotism before the British Medical Association a year ago, is to "acquaint its readers with the rudiments of practical therapeutic hypnotism, and to warn them against its dangers and difficulties." The writer is a follower of Bernheim, and, of course, a believer in the value of suggestive therapeutics, but in the present volume he omits all discussion of theories and controversial subjects, and gives a clear and careful account of the methods of hypnotizing, the indications for suggestive therapeutics, and the possible dangers and the means of avoiding them, with brief references to history and to the more distinctly psychological relations of hypnotism. He has succeeded in his aim of giving a readable and intelligent presentation of the rudiments of the subject, and his work is a good introduction to the more elaborate treatise of Bernheim.

*The Diseases of Personality.* By TH. RIBOT. Small 8vo, pp. 157. Chicago: The Open Court Publishing Co. 1891.

This work of Ribot is not unfamiliar to alienists, and the present translation in its convenient form will prove acceptable. It is rather a study of personal consciousness, and an analysis of the conception of the *ego*, as aided by the morbid phenomena of consciousness, than a clinical treatise on any group of diseases. The idea of personality is made up, according to the

writer, of a sum of all the sensations — not only of the transitory sensations which are, as some say, the sensations present in consciousness, but the vast undercurrent of organic sensations, seldom reaching the higher consciousness, but present in sub-consciousness. These, being stable, afford a basis for the stability of the idea of personality. "Personality results from two fundamental factors, the constitution of the body with the tendencies and sentiments that manifest it, and the memory." The disorders of personality are studied first under the heading of organic disorders, a study of personality as observed in double monsters and twins, and the changes observed in certain disorders of sensibility. The curious changes in personality in hysteria and various emotional disorders are then noted, the disorders as observed in insanity, and finally the dissolution of personality observed in the grave forms of dementia. There are three classes of derangements, the general sense of the body is completely changed, and an entirely new *ego* develops, perhaps with a memory of the past *ego*; there is alternation of two personalities, each perhaps ignorant of the other, and the new, second personality sometimes encroaching on the original; and finally a more superficial type of substitution of personality where the individual imagines himself to be some one else. It would have been of interest, under the second class, if the translator had added a reference to the more recent work of Janet.

*Records of the Association of Acting-Assistant Surgeons of the United States Army, A. D. 1891.* Edited by W. THORNTON PARKER, M.D., Recorder, A. A. A. S. Edition limited to 200 copies. Salem, Mass.: Salem Press Publishing and Printing Co. 1891.

The association of past and present acting-assistant surgeons of the United States Army who have served before, during or since the War of the Rebellion, was formed for the purpose of securing a correct history of those who served in this capacity, and also for mutual protection and benefit. Its members especially desire to obtain a better position for the acting-assistant surgeon. They desire that acting-assistant surgeons (now serving) many of whom have served long and faithfully, performing all the duties of commissioned surgeons, and many of whom are past the age permitting them to apply for examination for commissions as first-lieutenants in the medical corps, may be commissioned assistant surgeons with the rank of second-lieutenant of cavalry — not in the line of promotion — that they may have an established position and be no longer liable to discharge at the whim of the commanding officer.

The first meeting of the association was held at Newport, R. I., on June 24, 1889, Professor A. Reeves Jackson, of Chicago, presiding. At this meeting steps were taken to carry out the objects already mentioned, and also to bring about the possibility of membership in the Grand Army of the Republic for the contract surgeons. The acting-assistant (or contract) surgeons of the war, having never been commissioned, never received an honorable discharge, and the laws of the Grand Army of the Republic make such honorable discharge a prerequisite to membership.

The book contains the history of several of its members, some of whom served during the Rebellion, and some after. These lives differ in length and in modesty,

as doctors' autobiographies are apt to do; but as a whole, they are interesting as autobiographies an apt to be.

This association must strike most uninformed persons who first hear the name as a multiplication of useless associations; but no one can look through this report without gaining a respect for the object the association hopes to attain. The contract surgeons of the war included some of our brightest and best men, who look back with pride to the work they were able to do. It ought to be the policy of the Government to so treat its servants as to maintain their pride in their work and their love for their country.

*On Severe Vomiting During Pregnancy.* By GRAYLY HEWITT, M.D. 8vo, pp. 147. London: Longmans, Green & Co. 1890.

The basis of this essay is a paper read before the American Gynecological Society in 1888, which in turn is an amplification of a paper by the same author in 1871. The views of Dr. Hewitt on the etiology of the vomiting of pregnancy are quite well known, and to a certain extent quite generally accepted. He believes that the evidence of recorded cases shows that the vomiting is of reflex origin, the seat of irritation being in the uterus; further that the irritation is "an undue pressure or tension of the nerve filaments distributed in the walls of the cervix, especially those in the vicinity of the internal os, possibly to direct pressure on the cervical ganglion in some cases." "The alterations of the uterus proved by recorded cases to be most frequently present in cases of severe vomiting are: (a) marked flexion forwards or backwards; (b) rigidity of tissues of the cervix; (c) impaction or detention of the body of the uterus in the pelvis. These three factors are most frequently associated, in various degrees of severity."

The value of Dr. Hewitt's monograph consists largely in his array of cases, from which his deductions clearly and convincingly follow; but the fact remains that numerous cases of pregnancy-vomiting are observed for which no local cause can be found by expert examination,—cases which appear to be due to hyperæsthetic nerves, to emotional causes, to hysteria. Hewitt's views cannot, therefore, be accepted as of universal or indeed general application; but his work is of decided value as elucidating one phase of the subject, and as such must be welcomed as a positive addition to our knowledge.

*A Text-Book of Obstetrics, including the Pathology and Therapeutics of the Puerperal State. Designed for Practitioners and Students of Medicine.* By PROF. F. WINCKEL, of Munich. Translated from the first German edition by J. CLIFTON EDGAR, A.M., M.D., Philadelphia: P. Blakiston, Son & Co. 1890.

This is a complete and systematic treatise, a careful and adequate review of which is not warranted by the space at our command. The material upon which the book is based embraces the cases of the several clinics to which the distinguished author has been attached in Berlin, Rostock, Dresden and Munich; and also includes cases seen in the private practice of the author and of his father and grandfather. The book opens with an historical sketch, and a catalogue of text-books in all languages on this subject. The most prominent features of the work are the pathology and treatment of pregnancy and labor; but, as the title indicates, the puerperal state receives adequate attention, and there are twelve chapters on the

diseases of the new-born. Throughout the book, each chapter is headed with the literature of the subject, and there are 190 illustrations, which, with the exception of those of instruments, are entirely new.

The volume is somewhat ponderous, having over nine hundred octavo pages, and will doubtless seem appalling to a third year student; it will meet its greatest usefulness in the hands of advanced students and teachers, and will be found valuable for reference by the practitioner. Few men living have had greater opportunities for observation than Winckel in this department of medicine, and this work will place within the reach of his many admirers the fruits of his long and arduous years of professional activity.

*A Short Manual of Analytical Chemistry, Qualitative and Quantitative, Inorganic and Organic.* By JOHN METER, M.A., Ph.D., etc. First American, from the Fourth English edition. Edited by CLAUDE C. HAMILTON, M.D., Ph.G. Philadelphia: P. Blakiston, Son & Co. 1891.

This book is arranged on the principle of the course of instruction given at the South London School of Pharmacy. The first 150 pages are devoted to general qualitative and quantitative analysis. Then follow short chapters on certain special processes: one on the analysis of water, air and food, a second on the analysis of drugs and wine, a third on the analysis of gases, polarization, and spectrum analysis. The reviser has made some changes in the original text in order to adapt the book to use in this country. The chapter on urinary analysis has been enlarged and illustrated, and cuts of microscopic urinary sediments added; that on water analysis has been altered to correspond with Wauklyn's methods; certain special processes have been added, and several other minor changes made. The book is, on the whole, a fairly good one; not as complete as some, yet containing about all that is needed by the average chemical student. The most unsatisfactory part is the section on urinary analysis. About six pages are given to this important subject. Its treatment is therefore necessarily very superficial. The cuts give but a very imperfect idea of the microscopic appearances of the various urinary sediments. The subject of urinary analysis is one which should not, in our opinion, find a place in general text-books of analytical chemistry.

*Report on Cholera in Europe and India.* By EDWARD O. SHAKESPEARE, A.M., M.D., Ph.D., United States Commissioner, of Philadelphia, Washington: Government Printing Office. 1890.

This large and elaborate volume is the result of an executive order by President Cleveland, designating Dr. Shakespeare to proceed to such countries as were indicated, and to make a study of epidemic cholera. The work of investigation and labor of preparation was undertaken voluntarily, and without pay for personal services. Proceeding to Palermo and thence to Spain, the disease was studied in all its relations, and subsequently, in India much was added to the work. Not only the spread and hygienic surroundings found in the course of the disease, but also a careful and thorough study of the pathology of the disease and cultivation of the bacillus, appears in the volume (illustrated by numerous carefully prepared charts, maps and plates). For those interested in the study of this disease, and in the prevention of cholera epidemics, this publication offers much which is new and interesting.

## THE BOSTON

## Medical and Surgical Journal.

THURSDAY, DECEMBER 10, 1891.

A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DANRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

## THE PURIFICATION OF SEWAGE.

PART I of the Supplementary Report of the Massachusetts State Board of Health on Water-Supply and Sewerage, has already been commented on in a previous number of the Journal.<sup>2</sup> Part II deals with the important question of the means of rendering fouled water innocuous, and consists chiefly in statements of results of experiments at Lawrence, under the direction of the distinguished engineer, Hiram F. Mills, member of the board, to which are appended reports of chemical and bacteriological investigations, and upon nitrification of filth.

The experiment station, a description of which is given, was established to determine the fundamental principles of filtration not previously known, and to learn what can practically be accomplished by filters made of some of the widely varying materials found in suitable localities for filtration areas. Thirty-two different filters were used, and the results, chemically and biologically, are most fully recorded.

The distinctive and essential differences between continuous and intermittent filtration are presented by alternately using one method, then the other, upon the same filter, with the same daily quantity of sewage. It is shown that the efficiency of intermittent filtration depends upon the process of nitrification, which is proved not to occur in continuous filtration. The conditions favorable to nitrification, its dependence upon nitrifying organisms, and the condition of the surface and degree of saturation of the filtering material, are brought out by many examples, throwing much new light upon the subject. It is shown that while nitrifying bacteria are necessary in producing nitrification, the process of complete nitrification of the organic matter of the sewage is one of complete destruction of other bacteria, and, it is presumed, of all disease

germs. The process of purification of sewage by intermittent filtration is proved to be in no essential sense a straining process, but completed only when sewage passes down through a mass of coarse gravel in very slow motion, in extremely thin films over the surface of each stone, exposed to air, with the nitrifying bacteria, which exist in the sewage, attached to the surfaces of the stones. In intermittent filtration of water, only three hundred thousand gallons could be so far purified for six days in the week upon an acre as to cause the belief that the bacteria in it had been killed.

The results of experiments in cleansing sewage by chemical precipitation will be interesting to those towns where that is the best available solution of their sewage question.

The chemists and biologists add greatly to the value of the report in methods of analysis, in investigations into the nature of the changes which nitrogenous matter undergoes in the process of oxidation by filtration or chemical precipitation, and especially in accounts of means employed and results reached in bacteriological examinations. Among the micro-organisms in sewage, twelve species of bacteria are described with full illustrations from photomicrographs. Some bacteria evidently may pass through filters of coarse sand, but probably not through very fine sand.

The experiment station, in co-operation with the chemical and biological laboratories, has been the means of settling or corroborating some theories hitherto in doubt, and the generalizations therefrom cannot fail to be of great practical value.

## TUBERCULIN.

THE publication of Koch's last manifesto concerning tuberculin,<sup>1</sup> has called forth several opinions of this substance, and criticisms of Koch's work. Two of the more important of these, by Klebs<sup>2</sup> and Hueppe<sup>3</sup> form the basis of an editorial in the *Lancet* of November 14th.

Professor Klebs publishes a statement in anticipation of a more detailed work, in which he appears in the peculiar position of defending tuberculin against its own discoverer. Koch appears to believe that the injurious effects following large doses of tuberculin are due to the substance itself; whereas Klebs does not think so, and accounts for the fact that the same substance which acts curatively in animals produces injurious symptoms in man, by the explanation that animals are immune to the noxious elements of crude tuberculin. These injurious substances are, no doubt, alkaloidal in nature, and it is from these substances that Klebs has been trying to rid tuberculin. He has succeeded in extracting from the purified tuberculin of Koch the active substance without much admixture of these alkaloidal substances, and proposes to call

Experimental Investigation, by the State Board of Health of Massachusetts, upon the Purification of Sewage by Filtration and by Chemical Precipitation, and upon the Intermittent Filtration of Water. Made at Lawrence, Mass., 1890. Part II of Report on Water-Supply and Sewerage. Boston: Wright & Potter Printing Company, State Printer, 18 Post Office Square. P. 350.

<sup>2</sup> Vol. XXIV, p. 546.

it "tuberclocidin." It is an albumose, and it, or its combinations with tannin or other participants, has an undoubted effect in tuberculous, never exciting fever, and producing marked improvement. Hectic and night sweats disappear; signs of catarrhal process in the lungs, together with cough and expectoration rapidly diminish; appetite and body-weight increase. The bacilli in the sputum become granular, and less and less capable of receiving the staining reagents, and finally disappear.

Apparently neither Koch nor Klebs have taken any notice of the work in the same direction by Cheyne and Hunter, published last summer; in fact, Koch's paper has been widely criticised as containing a slight on all other bacteriologists.

Hueppe, among others, strongly protests against these "communications" of Koch's, and asserts that the latest of them contains nothing that had not been independently shown by others, whilst it does not go so far even as their work has in the isolation of the active principle of tuberculin. He quotes Professor Koch's earlier criticisms of M. Pasteur, against his own present methods of publication of his researches. And he might have added that no work of the French *savant* was ever produced with the air of mystery that did so much harm in the first announcements upon tuberculin. Finally, Dr. Hueppe deals severely with the accusations brought by Professor Koch against bacteriologists in general, and shows how ill-founded they are.

#### FRESH AIR IN AND ABOUT PUBLIC SCHOOLS.

At a stated meeting of the Medical Society of the County of New York, held November 23d, the following resolution offered by Dr. A. Jacobi, was adopted:

"Resolved, That the Board of Health be requested to use both its actual authority and its moral influence to secure for the school children a sufficient amount of air, light and accommodation, and to protect them from the dangers to their health, unavoidable in the present condition of the public schools."

This resolution was presented in consequence of a report, made by Dr. Henry E. Chapin, from the Committee on Hygiene, in regard to the sanitary condition of the public schools of the city; this report being supplementary to a very complete one on the same subject a year ago. Dr. Chapin recently investigated some of the schools referred to in the former report to see if any improvement had been made, but found little ground for encouragement. One of the schools visited was found, in fact, in a worse condition than last year. The great trouble in regard to the matter Dr. Chapin believed to lie in the fact that the responsibility was divided between three distinct bodies, namely, local boards of trustees, the Board of Education, and the Board of Estimate and Apportionment. While each had school functions to perform, not one of them had absolute power to originate and carry out needed reforms. In order to remedy this state of affairs he suggested that it might be well to call in the assist-

ance of the Board of Health, which was entirely independent of the other bodies mentioned, and he thought it would be wise to have a State law passed authorizing the Board of Health to exercise a constant sanitary supervision of the schools. Under such a law any defect in a school building could be promptly investigated by the Board of Health, and its recommendations for improvement should be made mandatory upon the body that should be found responsible. In case such recommendations were not acted upon within a reasonable time the Board of Health should have the power to close the school.

At a public meeting under the auspices of the newly organized "Union for Concerted Moral Effort," held on Thanksgiving night, a petition was drawn up and circulated, urging the necessity of more parks in the over-crowded districts of the city. It was addressed to the Board of Street Opening and Improvement of the City of New York, and called attention to the fact that under the existing laws this body had ample power to act in the matter. It also referred to the report on the subject made by the Board of Health in 1887, an extract from which reads as follows: "The school-houses of the city probably permit the best general indications for the location of parks of this character. Their number and situation are in great degree determined by the density of the population, and in tenement-house districts they are generally surrounded by high buildings which interfere seriously with their proper lighting and ventilation. It is difficult to over-estimate the advantage that would accrue to the city if it were made a matter of permanent policy to surround each public school building with a park of such dimensions as the circumstances of the case might warrant."

#### MEDICAL NOTES.

INFLUENZA, which for some weeks has been prevalent in several districts in different parts of Europe, is now reported from different parts of the United States.

MEDICAL MAYORS. — Fourteen cities in the United Kingdom have chosen medical men for mayors for the next year, among them Manchester, Stratford-on-Avon, Bristol and Edinburgh.

ETHER INTOXICATION. — A death in Paris, from ether taken as an intoxicant, has called attention to a habit which seems to have become prevalent recently in that city, of mixing ether with cognac as a beverage.

SMALL-POX IN CANADA. — On account of the prevalence of small-pox in parts of Canada, the Marine-Hospital Bureau, having received a request from the Governor of Michigan, have established medical inspection of emigrants at Detroit and Port Huron.

DR. E. VON ESMARCH, son of the distinguished surgeon of Kiel, has been appointed Professor of Hygiene in the University of Königsberg, in the room of Prof. C. Frankel, who recently accepted a call to Marburg.

**THE UNITED STATES MEDICAL PRACTITIONERS' PROTECTIVE ALLIANCE.**—The *Maryland Medical Journal* warns the medical profession editorially against this association, which has recently received a lengthy endorsement in the *Medical News*. "According to the published statement of the Medical and Chirurgical Faculty of Maryland, the 'founder' was expelled in April, 1890, from the State Medical Society of Maryland, for violation of its code of ethics (identical with the code of the American Medical Association); the offence, which is not there stated, being that he advertised himself in the daily papers, giving as an endorsement his membership in the Faculty, and refused to discontinue advertisement. The 'President' of this 'Alliance' is now Medical Director of the 'National Bureau of Medical, Surgical, and Hygienic Relief of Baltimore City,' the successor and heir of the 'Bureau of Medical Relief,' whose principles and practices are utterly condemned by all physicians of standing in Baltimore with whom we have conversed on the subject. We judge that this 'Alliance' collects from its members a membership fee (\$3); we cannot see what return it can possibly make for the investment."

**THE ILLNESS OF PRINCE GEORGE OF WALES** furnishes another popular clinical history of typhoid fever, which has been given in full in the English daily press. He first had headache on November 9th, and the disease was recognised on the 11th. Rose spots appeared on the 16th. The English royal family appear to be particularly liable to typhoid fever. The Prince of Wales had a very severe attack nineteen years ago, and the Prince Consort died of it thirty years ago. The Irish oysters, which were suggested as the source of the disease in Prince George's case, have since been vindicated.

**THE AUSTRIAN MEDICAL CHAMBER.**—A new council, to be called the *Aerztekammer* has been established by Act of Parliament in Austria. It will examine the character and conduct of its members, expunging names after sufficient testimony; it will also regulate the fees of medical men and lay down laws for the profession respecting benefit societies, insurance examinations, etc. Different medical societies have been endeavoring to have such a council created for the last twenty years.

**SUICIDE OF CHILDREN IN BERLIN.**—During the last fourteen months sixty-two suicides have been committed in this city by minors. Of these twenty-four were fifteen years old, fourteen had reached the age of fourteen, nine that of thirteen, seven of twelve and one of seven. Disappointed ambition and the fear of punishment are assigned as the causes of these acts.

**CHILD MARRIAGE IN INDIA** is said by a writer in the *Indian Appeal* to have had its origin at the time of the Mohammedan invasion. Conversion to Islam was the principal object of the Mussulman conquerors, and to facilitate this they began to marry by brutal force the girls of the Hindus. Cruel and oppressive as they were, they paid some respect, however, to the

married Hindu women. To secure the safety of Hindu girls, the institution of early marriages became indispensable. Gradually the practice developed into a superstition among the old men and women of Hindu families, who think their hearts will not be consumed on the funeral pyre if death were to intervene before they witnessed the marriage of their grandchildren.

**DISPENSARY ABUSE.**—The *Hospital Gazette* publishes the following satire on London medical charities: "The Managers of the Metropolitan Hospitals, observing that there is no such speedy or effective means of securing public sympathy as a monster demonstration in Hyde Park, have organized an imposing procession. The date is not stated, but the following is to be the programme:

"ORDER OF PROCESSION. — 1. Mounted GATE PORTERS. 2. FATTON CHARITY BARNACLE, Esq., representing the Secretaries and Treasurers, in a carriage drawn by four horses. 3. The Charters of various Charities, carried by their respective SECRETARIES, stating that they were founded for the 'Sick Poor.'" 4. THE SICK POOR in their own carriages. 5. Detachment of HOSPITAL CHRONICS bearing banners inscribed with the words, 'Free Physic,' 'Why Pay Doctors?' 'Come to the Copper Dispensary,' 'Shake the Bottle,' 'Plenty of Lotion,' 'Full Diet,' etc. 6. Six WATER CARTS loaded with Charity-Physic, which will play at intervals during the Procession upon 7. A detachment of ruined, or distressed, GENERAL PRACTITIONERS, accompanied by their care-worn wives and luckless offspring. 8. Staffs of 'Copper' and other DISPENSARIES. 9. HOSPITAL PHYSICIANS in carriages and pairs, each carrying an open umbrella inscribed with the words 'Under cover of a benevolent purpose.' 10. His Eminence, THE COLLEGE SKELETON."

**GIFT TO THE QUINCY (MASS.) HOSPITAL.**—The receipt of the sum of \$5,000, to establish a free bed, from the family of the late Nathaniel H. Emmons, of Boston, has been acknowledged by the trustees of the Quincy Hospital.

## Miscellany.

### THE NEW KOCH INSTITUTE.

The Berlin Society for Public Medicine held its first autumn meeting on October 26th, in the Koch Institute for Infectious Diseases, under the chairmanship of the Director of the Charité, Dr. Spinoia.<sup>1</sup> In addressing the meeting, Dr. Spinoia pointed out that the new Institute had appeared sufficiently important to the public health for the committee to make it desirable that the members should have an opportunity of inspecting it. Dr. Pfeiffer, the Director of the Scientific Department of the Institute, then gave an address, illustrated by means of electrical projections. He said the aim of the Institute was not limited to the study of tuberculosis, but to the discovery of effectual means of treating all infective diseases. Most exciters of disease belonged to the class of bacteria, of which many were already known. But there were a number of diseases of which the exciter was still unknown. These diseases would be systematically investigated, and it was to be hoped that unexpected discoveries would be made in regard to them. When we knew the exciters of these diseases, it would be the next aim to discover their vital conditions; It must also be determined through what channels they entered the system and how they spread themselves. If they

<sup>1</sup> Medical Press, November 13th.

succeeded in bringing about the still mysterious immunity, a great step in advance would have been made, and here also the subject was one not entirely conjectural.

Cure was not always brought about by way of immunity; sometimes spontaneous cure of tuberculosis took place. When substances were employed which in the animal organism excited the peculiar changes that led to spontaneous cure, one might hope for the cure in the human subject also. Tuberculin was undoubtedly such a substance, and it was being subjected to still further investigation. The Institute had lofty aims, and if Koch's discoveries resulted in no more than its foundation, his labors had been sufficiently blessed.

### DIURETIN.

KRESS,<sup>1</sup> in a paper reviewing what has already been written on this drug, and describing in detail his own observations in a large number of cases, comes to the following conclusions. Diuretin is a true diuretic, increasing equally the fluid and solid constituents of the urine. Its action is due to a direct, unirritating influence upon the renal parenchyma; albumen does not appear in consequence of its action, and if already present in the urine its amount is not changed. The frequent favorable influence of the drug upon the organs of circulation is probably produced indirectly. The best results from its use are obtained in cases of acute and chronic diseases of the heart and kidneys, especially acute nephritis and uncomplicated valvular disease. Good effects may be expected in chronic nephritis, and myocarditis, whereas in simple serous effusions, as in tuberculosis, the drug is of no use.

Diuretin can be continued for a long time in large doses, two drachms a day, without any alarming secondary effects. The continued administration of the drug in cases of the above-mentioned diseases, does not decrease its diuretic action.

A similar series of observations is recorded by Pfeffer,<sup>2</sup> who strongly recommends diuretin, especially for cardiac dropsy and chronic renal disease. When compared with digitalis, however, diuretin is found inferior as a cardiac stimulant, while superior in its action on the kidneys. Pfeffer's conclusions in other respects resemble those of Kress.

### JAUNDICE.

At the fourth Italian Congress of Internal Medicine, held in Rome in October, Professor Patella in his report on jaundice proposed the following conclusions:<sup>3</sup>

Neither the "hemafecal icterus" of Gubler, the "urobilin icterus" of Gerhardt, nor the "biliubin icterus" of Tessier can be sustained.

Hemato-genous icterus does not exist.

Nearly all the forms of jaundice seen clinically come under the hepatogenous form by resorption.

The mechanism of the production of some forms of icterus is very obscure — that is, the reasons *why* and *where* this biliary resorption takes place.

The physio-pathological conception of so-called catarrhal icterus, as maintained in the past, is no longer

sufficient to explain the actual mechanism of its production.

The actual state of our knowledge of the bacteria of the intestinal canal and biliary passages does not authorize us to accept without reserve the infective origin of catarrhal icterus.

Chauffard's idea of its toxic origin — modified in accordance with the results of biologic chemistry and experimental studies on icterus — must be taken into serious consideration in catarrhal icterus, and especially in certain cases of infective jaundice.

Catarrhal icterus can be considered the first link of a chain which, starting from it, reaches to grave and lethal icterus. A plural etiology — a true multiplicity of pathogenic possibilities — must nowadays be given to infective jaundice.

The "morbus Weil," though belonging to this group on account of its clinical aspects, even in the absence of bacteriological or pathological demonstrations, merits, however, a special place, as etiologically specific. Is it bacteric or toxic?

Our present knowledge of biliary infection is incomplete and imperfect.

### IMMUNITY AND INFECTION.

DR. A. C. ABBOTT, in an interesting paper<sup>1</sup> on some of the more important contributions to medical literature on the subject of immunity, describes briefly the work recently done by several experimenters. As the result of this work, he offers the following as the present state of our knowledge of immunity and infection:

Of the hypotheses that exist for the explanation of immunity, that which assumes acquired immunity to be due to reactive changes on the part of the tissues has received the greatest support. Immunity is most frequently seen to follow the introduction into the body of the products of growth of bacteria that in some way or other have been modified. This modification may be artificially produced from the products of virulent organisms and then introduced into the tissues of the animal; or the organisms themselves may be so treated that they are no longer virulent, so that when introduced into the body of the animal they eliminate poisons of a much less vigorous nature than is the case when they possess their full virulence.

Immunity following the introduction of bacterial products into the tissues is not the result of the permanent presence of these substances *per se* in the tissues, or to a tolerance acquired by the tissues to the poison, but is probably due to the formation in the tissues of another body that acts as an antidote to the poisonous substance. This protecting protoid that is eliminated by the cells of the tissues need not of necessity be antagonistic to the life of the organisms themselves, but in some cases must be looked upon more as an antidote to their poisonous products.

In the serum of the normal circulating blood of many animals there exists a body that is capable, outside of the body, of rendering inert bacteria that, if introduced into the body of the animal, would prove infective.

In many instances, infection may be looked upon as a contest between the bacteria and the tissues, carried on on the part of the former by the aid of the poisonous products of their growth, and resisted by the latter

<sup>1</sup> *Munchener medizinische Wochenschrift*, September 22.

<sup>2</sup> *Centralblatt, f. d. gesamm. Med.*, 1891. Paris VII and IX.

<sup>3</sup> *Medical News*, November 24th.

*Medical News*, November 7th.

through the agency of proteid bodies normally present in their integral cells. When infection occurs it may be explained either by the excess of vigor of the bacterial products over the antidotal or protective proteids eliminated by the tissues, or to some cause that has interfered with the normal activity and production of these bodies by the tissues.

Phagocytosis, though frequently seen, is not essential to the existence of immunity, but is more probably a secondary process; the bacteria being taken up by the leucocytes only after having been rendered inert through the normal germicidal activity of the serum of the blood and other fluids of the body.

### THE NEUROTIC CHARACTER OF INFLUENZA.

DR. JULIUS ALTHAUS, in a recent paper<sup>1</sup> on the neurotic character of the grip, says that the great varieties observed in the symptoms of the feverish attack of grip have induced a number of observers to assume three different forms of the disease: the nervous, catarrhal, and gastric variety. The author is, however, convinced that these three forms have not any different pathological characters, but that influenza is always a true nervous fever, the symptoms of which only differ as far as localization of the grippo-toxine in different areas of the nervous system is concerned, and that the three forms just mentioned are perfectly arbitrary, all the symptoms of the feverish attack of influenza are referable to irritant poisoning of a definite centre of the nervous system. Shortly after the visitation of influenza had commenced, a number of patients complained of severe forms of neuralgia, loss of power, and a general break-up of the nervous system, which they attributed to an attack of grip. Some of these patients had been in perfect health before, while in others a neurotic pedigree or a previous syphilitic infection, or some other constitutional fault could be clearly traced, upon which the subsequent nervous affection had, as it were, been grafted.

In comparing those nervous troubles which may be met with after such diseases as diphtheria, typhoid fever, scarlatina, small-pox, measles, erysipelas, and malaria with those seen after influenza, it soon became evident that as a powerful etiological factor of all kinds and forms of nerve disease influenza stands *facile princeps* among all infectious fevers. The only distemper which approaches grip in this particular quality is syphilis, which may also give rise to the symptoms of almost any nervous disease. A still further analogy between these two infectious diseases, is found in the circumstance that in both we may have a primary attack, secondary symptoms of a comparatively mild character soon afterwards, and tertiary affections of a more dangerous and obstinate nature, affecting the organic structure of tissues, at a more remote period.

Grip also seems occasionally to revive an old syphilitic infection which has lain dormant for years, and thus indirectly to give rise to certain diseases of the spinal cord, which are known to occur habitually on a syphilitic base. In comparing the degree of virulence of the two poisons, however, the author has found that when the grippo-toxine attacks the structure of organs, it often does so with far greater ferocity and in a more ruthless manner than the syphilitic virus. The

question then arose whether the chief reason of this peculiarity might not be found in the circumstance that the distemper itself, in its primary manifestations, is not so much an infectious catarrhal fever, as has been generally assumed, as an infectious nervous fever. A clinical survey of the symptoms of the feverish attack rendered this, *primâ facie*, not unlikely, as many of them, such as headache, utter prostration of mental and bodily strength, delirium, coma, convulsions, etc., point unmistakably to the nervous system as their starting-point; while, on the other hand, catarrh of the mucous membranes and pneumonia have been completely absent in a large proportion of cases. Indeed, many patients have had influenza badly without having once coughed or squeezed.

The author refers to the evidence of the value of vaccination and revaccination in lessening susceptibility to the disease, and recommends, in case another outbreak seems imminent, that some provision be made for extensive revaccination of those exposed.

### MENTAL DISEASE FOLLOWING INFLUENZA.

In the *Deutsche Medizinische Zeitung* for September 3d and 7th, there are references to various recent articles on mental disturbances following influenza.<sup>1</sup> Two of these articles merely give an account of one or two isolated cases, but in the others there are records of more considerable numbers of patients who had developed a psychosis following on influenza. Some of those referred to by Dr. Jutosiuski<sup>2</sup> were observed in Professor Jolly's clinique in Strassburg. The conclusions in his paper are summarized as follows:

When mental disease is brought on by influenza, in the great majority of cases the patients are of neurotic temperament. The attack may come on in any stage of the influenza, but there appears to be a preference for the period of convalescence. In the majority of cases the symptoms were those of melancholia and hypochondriasis. Neither sex is specially liable. Most cases occur between twenty and fifty years of age. In the case of existing mental disease, influenza caused an aggravation in almost every instance.

With these statements may be compared the facts submitted by Dr. Mispelbaum.<sup>3</sup> He had patients of each sex, and of ages varying from sixteen to seventy. All of them had been for some time convalescent from the influenza attack, though suffering from lassitude and persistent sleeplessness. At the onset of the psychosis there was always acute delirium, of variable duration, which gave place, except in two cases, to a melancholia lasting for at least a fortnight. With Kraepelin, he does not consider that influenza of itself is sufficient to produce an insanity in a normal subject, but that there must always be other etiological factors. In any case, influenza must be considered along with other specific fevers which have mental diseases among their sequela.

Mispelbaum mentions other nervous diseases which he had met with after influenza (intercostal and supra-orbital neuralgias, and long-continued sleeplessness). He advises special care in treatment and observation of cases during the period of lassitude following influenza.

## THERAPEUTIC NOTES.

**MALARIA.**—Guttmann and Ehrlich<sup>1</sup> recommend chemically pure methyl blue in doses of a grain and a half five times a day between the periodic attacks of malaria. The treatment should be continued for a week or more after the disappearance of fever.

**DIPHTHERIA.**—Gaucher<sup>2</sup> treats this disease as follows: The membranes are detached as far as possible with a piece of wood wound with cotton. The following is then applied to the raw surfaces two or three times:

R Camphor . . . . .	20 parts.
Olei ricini . . . . .	15 parts.
Alcohol absol. . . . .	10 parts.
Acidi carbonici . . . . .	5 parts.
Acidi tartarici . . . . .	1 part.

This acts as a caustic. The throat should then be frequently irrigated with a one per cent. carbolic solution if possible, otherwise with hot water or a weaker solution. This series is repeated every few hours.

**MERCURY IN TYPHOID FEVER.**—From a study of nearly 700 cases, Smakovsky<sup>3</sup> concludes that the simplest and most efficacious treatment consists in the administration of calomel in fractional doses. Three-fourths of a grain is given every hour for ten doses, if necessary, or till copious, soft, greenish stools have been secured, a gargle of chlorate of potash being meanwhile used to prevent stomatitis. In cases in which cardiac weakness already exists, an infusion of digitalis is used before the calomel. A second course of calomel may be given a day's interval after the first. During the interval and subsequently, the author prescribes:

R Subnitrate of bismuth . . . . .	gr. iiss.
Pure naphthalene . . . . .	gr. 3-30.
Sulphate of quinine . . . . .	gr. iiss. M.
Sig. One powder. Four of these daily.	

**HYDROPHOBIA.**—In order to determine whether the disease is really hydrophobia, the following method is recommended by a Chinese contemporary: Get a gong or any large brass utensil and strike it before the patient. If he is suffering from hydrophobia he will at once show signs of madness; then fan him with a large palm-leaf fan, and he will crouch down as if in great fear. When the presence of the disease is thus ascertained, the next step is to search the hair of the patient. There will certainly be found one hair of the color of vermillion, and rather stronger and coarser than ordinary hair. This particular hair should be entirely pulled out, not even the smallest part of the root must be left, otherwise the disease cannot be cured. When this has been done a prescription must be prepared, and the drugs used should be of such a nature as will expel the poison from the place in which it is.

**GELSEMIUM FOR COLDS.**—Dr. Auble<sup>4</sup> in an article on "A Bad Cold" recommends gelsemium. Ten drops of a reliable fluid extract (assay d.) are dissolved in three ounces of water, and of this mixture the patient takes a teaspoonful every ten or fifteen minutes for an hour, then at less frequent intervals according to the effects produced. The plan is simple, the medicine harmless in the dosage recommended, and not at all unpalatable.

## METEOROLOGICAL RECORD.

For the week ending November 21, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro- meter	Thermo- meter.	Relative humidity.	Direction of wind.	Velocity of wind.	Wet'th. °	Rainfall in inches.

each. From measles New York 4, Chicago 2, Fall River 1. From croup New York and Brooklyn 2 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,108, for the week ending November 7<sup>th</sup>, the death-rate was 19.3. Deaths reported 3,486: acute diseases of the respiratory organs (London) 329, diarrhoea 95, fever 8, whooping-cough 65, measles 60, scarlet fever 38, diphtheria 34.

The death-rates ranged from 13.2 in Halifax to 28.6 in Sunderland, Birmingham 17.3, Bradford 16.8, Huddersfield 16.9, Hull 17.1, Leeds 19.1, Leicester 16.8, Liverpool, 26.1, London 17.9, Manchester 22.7, Newcastle-on-Tyne 23.4, Nottingham 15.9, Portsmouth 16.0, Sheffield 17.2, Wolverhampton 25.2.

In Edinburgh 21.9, Glasgow 27.9, Dublin 31.4.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,405,108, for the week ending November 14<sup>th</sup>, the death-rate was 20.6. Deaths reported 3,707: acute diseases of the respiratory organs (London) 370, whooping-cough 109, measles 93, diarrhoea 69, fever 59, diphtheria 42, scarlet fever 30.

The death-rates ranged from 15.1 in Leeds to 33.0 in Sunderland; Birmingham 22.8, Bradford 16.3, Hull 17.9, Leicester 18.9, Liverpool 24.8, London 19.6, Manchester 27.9, Newcastle-on-Tyne 24.7, Nottingham 18.1, Salford 20.5, Sheffield 17.0.

In Edinburgh 26.1, Glasgow 29.5, Dublin 28.8.

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 28, 1891, TO DECEMBER 4, 1891.

FIRST-LIEUT. PAUL SHILLOCK, assistant surgeon, U. S. A., is relieved from duty at Fort Yates, N. D., and ordered to Fort Grant, Arizona, for duty.

FIRST-LIEUT. WILLIAM N. SUTER, assistant surgeon, U. S. A., is relieved from further duty at Fort Grant, Arizona, and assigned to duty at Fort Bowie, Arizona.

CAPTAIN WILLIAM O. STEPHENSON, assistant surgeon, U. S. A., is relieved from duty at Columbus Barracks, Ohio, and will report in person to the commanding officer, Fort Niagara, N. Y., for duty at that post.

CAPTAIN ARTHUR W. TAYLOR, assistant surgeon, U. S. A., having been found incapacitated for active service by an Army Retiring Board, will proceed to his home.

Leave of absence for one month is granted CAPTAIN LOUIS M. MATS, assistant surgeon, U. S. A.

The leave of absence granted CAPTAIN ROBERT R. BALL, assistant surgeon, U. S. A., is extended one month.

#### OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 5, 1891.

T. C. HELL, surgeon, placed on the retired list, December 3, 1891.

W. H. JONES, surgeon, promoted to Medical Inspector, November 14, 1891.

FRANK ANDERSON, passed assistant surgeon, promoted to surgeon, November 14, 1891.

N. J. BLAKEMORE, assistant surgeon, from Navy Yard, League Island, Pa., and to the U. S. S. "Miantonomah."

LEWIS MORRIS, assistant surgeon, ordered to the Navy Yard, League Island, Pa.

#### OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE UNITED STATES MARINE HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING NOVEMBER 28, 1891.

VASSANT, JOHN, surgeon. Leave of absence extended ten days. November 24, 1891.

HAMILTON, J. B., surgeon. Detailed for special duty. November 24, 1891.

LEWIS, FREDERICK, surgeon. To proceed to Cape Charles Quarantine for duty. November 24, 1891.

CARLIS, H. R., passed assistant surgeon. To proceed to Savannah, Ga., for temporary duty. November 19, 1891.

BAKER, C. L., passed assistant surgeon. To proceed to Boston, Mass., for special duty. November 19, 1891. To proceed to Washington, D. C., on special duty. November 21, 1891.

KATHORP, P. C., passed assistant surgeon. Relieved from duty at San Francisco, Cal., ordered to Boston, Mass. November 20, 1891.

WHITE, J. H., passed assistant surgeon. To proceed to Harris Island, Tex., for special duty. November 17, 1891.

CARLSON, P. M., passed assistant surgeon. To proceed to Harris Neck, Ga., for special duty. November 19, 1891.

WILLIAMS, L. L., passed assistant surgeon. Granted leave of absence for twenty-nine days. November 14, 1891.

PETTUS, W. J., passed assistant surgeon. Relieved from duty at Cape Charles Quarantine; ordered to Buffalo, N. Y., for temporary duty. November 25, 1891.

PERRY, T. B., passed assistant surgeon. To rejoin station at Baltimore, Md. November 19, 1891.

COBB, J. O., assistant surgeon. Granted leave of absence for twenty-one days. November 13, 1891.

YOUNG, G. B., assistant surgeon. To proceed to Memphis, Tenn., for temporary duty. November 13, 1891.

#### SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held on Monday, December 14, 1891, at the Medical Library, 19 Boylston Place, at 8 o'clock p.m. Dr. J. C. White: "Some Dangers of Infection Incidental to Professional Life." Dr. H. L. Burrell: "What is a Felon?" Balloting for candidates for membership will begin at 9 o'clock.

G. G. SEARS, M.D., Secretary.

MASSACHUSETTS MEDICAL SOCIETY, SUFFOLK DISTRICT. — The Section for Clinical Medicine, Pathology and Hygiene, will meet at 19 Boylston Place, on Wednesday, December 10<sup>th</sup>, at 7.45 o'clock p.m.

Papers: Dr. Walter Channing: "Casts of the Mouth and Palate in Idiots." Prof. Thomas Dwight, of Harvard University, will open the discussion.

Dr. V. Y. Bowditch: "The Establishment of Sanitaria for Pulmonary Diseases in the Immediate Vicinity of our Large Cities." Drs. F. I. Knight and A. L. Mason will open the discussion.

Pathological Specimens.

Refreshments after the meeting.

ALBERT N. BLODGETT, M.D., Sec'y, 300 Boylston St.  
E. G. CUTLER, M.D., Chairman.

#### APPOINTMENT.

WILLIAM F. WHITNEY, M.D., has been appointed Professor of Parasites and Parasitic Diseases in the Harvard School of Veterinary Medicine.

#### RECENT DEATHS.

CHARLES D. SMITH, M.D., of New York, died December 4<sup>th</sup>, aged seven-eleven. He graduated from the University of Pennsylvania in 1837. He served as surgeon during the war, and retired from practice shortly after its close.

HERBERT G. LITTLE, M.D., of Long Island City, died December 1st, aged thirty-nine.

DR. IGNATIUS HIRSCHLEK, a well-known ophthalmic surgeon and writer on diseases of the eye, died in Buda Pesth, November 11<sup>th</sup>, aged sixty-eight.

DR. HENRI ROGER, a distinguished physician of Paris, died recently aged eighty-two. He was made president of the Académie de Médecine in 1880.

THOMAS WHARTON JONES, F.R.S., F.R.C.S., a distinguished English physiologist, died November 7<sup>th</sup>, aged eighty-three.

#### BOOKS AND PAMPHLETS RECEIVED.

Proceedings of the New York Pathological Society for the year 1890.

The Seventieth Birthday of Virchow. Celebration in the Johns Hopkins University.

Who can be Medical Experts? By Henry A. Riley, Esq., of New York. Reprint. 1891.

Is a Child Viable at Six and a Half Months? By Llewellyn Eliot, M.D., Washington, D. C. Reprint. 1891.

Cookery for the Diabetic. By W. H. and Mrs. Paolo, with preface by Dr. Favay. London: Longmans, Green & Co. 1891.

Transactions of the Ophthalmological Section of the American Medical Association at the forty-second meeting, held at Washington, D. C., May 5-8, 1891.

The Supreme Passions of Man; or the Origin, Causes, and Tendencies of the Passions of the Flesh. By Paul Piquin, M.D. Battle Creek, Mich.: The Little Blue Book Co. 1891.

A Vegetable Plate: also a New Technique in Intestinal Anastomosis. By Robert H. M. Dawbarn, M.D., Professor of Surgical Anatomy and Operative Surgery, New York Polytechnic.

The Bilateral Paroses and Pseudo-Plegias of Childhood, with special Reference to a Type of Malarial Origin. The Arrangement of the Supra-Cerebral Veins in Man, as Bearing on Hill's Theory of a Developmental Rotation of the Brain. By William Browning, M.D., Brooklyn, N. Y. Reprints. 1891.

## Address.

THE PRINCIPAL TYPES OF PHYSICAL TRAINING COMPARED.<sup>1</sup>

BY EDWARD MUSSEY HARTWELL, PH.D., M.D.,

Director of Physical Training in the Public Schools of Boston.

At our first meeting, I stated that the aim of these lectures was a practical and pedagogical one, namely, to set forth the teachings of experience and science touching the nature and effects of physical training in support of my main contention that it is not only wise and desirable, but necessary and practicable as well, to make bodily exercise an integral and co-ordinate part of the elementary and higher education of American youth of both sexes. Attention was called to the pronounced interest evinced by this community in matters pertaining to bodily exercise and education, and to the forms in which that interest was most striking and manifest: (1) In the field of athletic sports; (2) in the field of discussion and controversy; and (3) in the field of gymnastics and drill. Emphasis was laid upon the fact that, although the interest in question had marked local characteristics, this apparently circumscribed and distinctively "Boston Movement," was, in truth, only a part of a wider, general movement embracing other parts of this country and many parts of Europe—the fact being that educational authorities have been put upon the defensive, all over the civilized world, by reason of the alarming results of their inability, or unwillingness, to modify their methods in accordance with the plain teachings of experience and of modern science as to the interdependence of body and mind.

At our later meetings we have considered the more salient features of what may be denominated the most representative and typical forms of physical exercise or training. These are five in number and may be styled: the Grecian; the Mediæval; the British; the German; and the Ling or Swedish. We have also discussed the nature and effects of muscular exercise, from the standpoint of modern physiology, in order to secure a standard or criterion, by which to estimate the hygienic and educational value of any particular system of exercise.

In comparison with the five main types or national systems of exercise, mentioned above, all other schemes and so-called systems of physical education, seem to me, to be fragmentary, anomalous, and insufficient. Provided we apprehend the lessons of experience and the teachings of science with regard to the essential character and comparative worth of the results attained by each of these national systems of bodily education, we shall be able to classify and criticise, with approximate justness, the numerous varied, and often fantastic, new and local schemes of exercise, whose inventors and partisans are on every hand clamoring loudly and insistently for recognition and patronage. I shall not consider them further, as it is not my purpose in these lectures to attempt to bolster up or pull down any local idol that has gained a hierarchy or worshippers for itself, either in this city or in the country at large.

A twofold comparison of the systems whose origin and more obvious external features have thus far occupied our attention, seems to me to be desirable. I

propose, therefore, to compare them, in the time which remains to me, first from the historical point of view, in order to discover the place and influence attained by the five typical systems in the life and history of those nations which have originated or adopted them; and in the second place, to compare them as regards their fitness to realize the true ends of bodily education, taking as my criterion so much of the modern doctrine of the nature and effects of exercise as seems necessary for my purpose.

It will be convenient to use the terms *agonistic*, *gymnastic* and *athletic*, in speaking of the most general features of the five types of physical training under review, these terms being derived from Grecian usage. An *ἀγων*, you remember, meant originally an assembly, then an assembly to witness a contest of some sort. For instance, the Olympic games were *gymnic agones*, being so-called because the contestants in them were naked; then there were musical and hippic *agones* also. The prizes given to victors in an *ἀγων* were termed *ἀλζα*, and an *athlete* was a winner or contestant simply; later, in its worse sense, an *athlete* was a *prize-fighter*, governed by professional and mercenary ends. A gymnast was a trainer primarily, especially after the agonistic games had become systematized and regulated, and were practised as a necessary part of the education of every free-born youth.

Greek physical training was, then, *agonistic*, during the period of its growth, when its main purpose was to afford sport or pastime; it was *gymnastic* during the period of its best estate, about the time of Pericles, when its aims were distinctly educational and ethical; and it became *athletic*, in the worse sense of the word, during the decadence of the institutions and independent life of the Greeks when a spirit of mercenary self-seeking and professionalism dominated both gymnasts and athletes.

Using these terms, in the sense above indicated, we should call the martial exercises of the ancient Gauls and Teutons, *agonistic*. Out of these sports and exercises were developed the physical training of the young page and squire, and the chivalric tournaments and jousts to which the knights of Italy, France, Germany, England and Scandinavia were so devoted in feudal times. That training and these contests were partly *agonistic* and partly *athletic* in their nature. The same terms may be applied to British sports. They were *agonistic* and have become chiefly *athletic*, within the last seventy-five or one hundred years. Athleticism is the dominant note in all British physical training, which has but little of pedagogical aim or method in it, and is less deserving of being called *gymnastic* than was the mediæval kind of physical training. German turning is somewhat *agonistic* in its nature, though its aims and methods are in the main *gymnastic*. No system of physical training, ancient or modern, so well deserves the name of *gymnastic* as the Swedish system, which has, perhaps, too little of the athletic element in it. In the Swedish gymnastics, moreover, we find medical gymnastics more highly developed and accorded a higher place than in any other system of physical training. Indeed, excepting the Grecian, there is, properly speaking, no system of medical gymnastics, worthy the name, to be found outside of the Swedish gymnastics.

Taine has well said, in his "English Notes," "In every age, under every civilization, a people is always

<sup>1</sup> The substance of this article was delivered on May 9, 1891, at the last of Six Hemenway Lectures on Physical Training, by the writer, at the Old South Meeting House, Boston.

itself. Whatever be its dress, goat-skin, blouse, gold-laced dondlet, black dress-coat, the five or six great instincts which it possesses in its forests follow it in its palaces and offices." Of these great instincts, the play instinct is one of the most ineradicable. To this instinct of the barbarian and the child, as to a primitive germ, we may trace more or less directly every national or tribal system of bodily training. Ball-games, contests in running, jumping, lifting and casting of weights, hurling a tree-trunk or a beam and wrestling, are sports which have never ceased to be practised in one form or another, as popular pastimes and means of exercise from Homer's time to our own.

In many an out-of-the-way corner of Europe, especially in remote islands and secluded mountain-districts, you may find to-day one or another of the ancient pastimes still popular and played according to immemorial custom,—often on the anniversaries of ancient heathen festivals, which the Church has never been able to render wholly Christian, although most of them have been duly christened. The ancient sports have undergone least change in such regions as the Scottish Highlands, the Lake Country of England, outlying districts such as Friesland and Gothland, and the valleys of the Alps, Tyrol and Pyrenees.

If we attempt to trace our typical systems of physical exercise to their original forms, we find them beginning either in childish plays, or in games which are akin to such plays. The Grecian gymnastics and athletics developed directly out of such pastimes as Ulysses and Ajax engaged in around the funeral pyre of Patroclus which Achilles instituted in honor of his playmate and comrade. Jahn adopted several of the ancient German games in his turning system, and Ling wrote about the sports of the ancient Norsemen, though he gave them no very prominent place in his gymnastic system. British sports are the most highly developed modern expression of the play instinct. It is a significant fact that French, Swedish and even some German educators are now endeavoring to domesticate British sports, in order to incorporate an athletic element in their more systematic and refined forms of physical training; though it has been truly pointed out by foreigners, that "English school-boys play at their work, and work at their play," when judged by continental standards.

The words play and exercise were quite synonymous in the early days of our English speech, the ancient Teutonic word *plega*, play, being applied to all sorts of warlike exercises. For instance, we find it in such forms as *linden-plega*, play of shields, *sweardu-plega*, sword-play. The Anglo-Saxon translated the Latin *gladiator* into *plegere* or *plegeman*, meaning player. In Bede's "Ecclesiastical History," one finds that the priest was forbidden to hunt, hawk, or dice, but was charged "to play with his book, as became his condition." In the time of Henry the Eighth, "plaienge at weapons" was still a necessary branch of the education of young noblemen. Sword-play and cudgel-play still retain their ancient meaning of practice as well as of amusement.

Hodgetts, in his "The English in the Middle Ages," recounts the story, given in the "Edda," of the death of Baldur, the son-god, by means of an arrow made of mistletoe, on which the traitorous Loki was sitting in the shape of a white crow, at the time Nauma, the bride of Baldur, obtained the promise of all nature,

but the mistletoe, not to injure her spouse. So, when the gods of Valhalla instituted a game, which consisted in throwing their spears, javelins and arrows at Baldur, who was placed with his back against the holy-tree, that is, the holly-tree, Loki managed to have Höder, the blind twin-brother of the shining one, shoot the arrow of mistletoe at Baldur, who was unscathed by the missiles of the other gods. Baldur was killed by the arrow of mistletoe, which had first transfixed the cock, which flew up to intercept the arrow, and has been sacred to Baldur ever since.

"I only refer to this myth," said Hodgetts, "to show you where to look for the origin of the early English or Anglo-Saxon archery games, their casting the bar and javelin at a figure armed as a warrior, and the custom of shooting at the cock at Easter." Cock-throwing was, till rather recent times, I may add, a customary game among British school-boys at Shrove-tide.

The old English custom of playing certain games in the church-yard, and even the church itself, had doubtless a pagan origin. Among certain "Instructions for Parish Priests," dating from the middle of the fifteenth century, we find one with regard to profanation "wyth-yune chyrebe seywtwary," which runs as follows:

"Songe and cry and snehe fare,  
For to stynte thow schalt not spare;  
Castyng of axtre and eke of ston,  
Sofere hem ther to vse non;  
Bal and bares and snehe play,  
Out of chyrecheyorde put a-way;  
Courte holdyng and snehe maner chost,  
Out of seywtwary put thow most."

Archery, under the name of artillery was for many centuries a common exercise in England, being particularly protected by statute, even as late as the time of Henry VIII, when every village and many schools had butts for archery practice. In a law of Richard II, passed in 1388, it is enacted that "Servants and Labourers shall have Bows and Arrows, and use the same the Sundays and Holydays, and leave all playing at Tennis or Football and other games called Coits, Dice, Casting of the Stone, Skittles, and other such importune Games." Though the above contains no mention of church-yard games as such, it was held, long after the reign of Richard II, that "The Lord of the Manor may not, by custom, plough or break up two acres of land lying near the church, because it was anciently granted for the recreation of the youth, after evening service on every Lord's Day." King James I, being a hater of Puritanism and its kill-joy tendencies, in 1618 issued a proclamation known as "The King's Book of Sports," in which he declared his pleasure to be, "that after the end of Divine Service our good people be not disturbed, letted or discouraged from any lawfull recreation, such as dancing, either of men or women. Archery for men, leaping, vaulting, or any other such harmless Recreation, nor from having May Games, Whitson-ales, and Morris-dances, and the setting up of Maypoles, and other sports therewith used, so as the same be had in due and convenient time, without impediment or neglect of Divine Service." In 1633 Charles I reissued the "Book of Sports."

All this seems to indicate that old English sports, at least in pagan times, had originally a relation to public worship, somewhat similar to that of the Greek games, to funeral sacrifices and other acts of worship.

Although differing widely in most respects, the Grecian and British types of bodily education are alike in being devoid of any admixture of elements acquired through imitation or borrowing. British sports reflect more fully, perhaps, than any modern system of physical training, the national spirit of their devotees. In them we find clearly mirrored certain traits of British character, such as marked individualism, ruled by tradition and ancient custom; a dislike of theoretical and ideal aims; a liking for strenuous exertion and violent methods; a marked tendency to contentiousness; and a preference for what is concrete and resistant. They are the necessary, inherited, pastimes of a manly, vigorous, self-sufficient folk; and have never fully outgrown or lost their primitive, not to say pagan, characteristics. They have been followed largely for their own sake, and have suffered but slight modifications through the efforts of innovating educators and thinkers: in this respect presenting a marked contrast to German Turning and Swedish Gymnastics, which, though they bear the impress of national feeling, have been developed chiefly of set purpose, on the part of their promoters, either as a means of national regeneration, or as a remedy for over-refinement and the deteriorating effects of sedentary and urban life. Such modifications as are inevitable in British sports, are due mostly to efforts to make them more social and general, in short, — more truly popular. Then, too, the English climate is singularly favorable for the pursuit of athletic sports. The summer is so cool and the winter usually so mild in England, that there are comparatively few days in the year when one may not, if he will, engage in out-of-door games of some sort. Indeed the climate, more than most climates, acts as an incentive or provocative to active exercise. Muscular activity is more conducive to comfort, than is quiescence or loafing, in most varieties of English weather. Riding is always in season. Football is practicable not only throughout the autumn and winter, of ordinary winters, but far into the spring. Rowing may be practised more than three-quarters of the year. Cricket, being dependent on the state of the turf, is little played but in the spring and summer.

The English public schools are peculiarly adapted to serve as the nurseries of national pastimes. The oldest of them, Winchester and Eton, were originally ecclesiastical foundations, and have served, in a measure, as models for most of the later foundation schools, which, as a class, have departed less widely from their mediæval prototypes than have the secondary schools on the Continent. In England the public schools, which are boarding schools for boys from ten or twelve to nineteen years of age, enjoy a practical monopoly of secondary education. On the Continent, if we except the French Lycées, high class boarding schools are the exception. Moreover, the continental standard of intellectual training is higher and the methods of instruction more exacting and severe, so that pupils in a German, Swiss or Scandinavian *Gymnasium* or in a French *Lycée*, have much less freedom and leisure than boys at Eton, Rugby, or Winchester, where the half holidays average three a week. Force of public opinion generally, and often the rules of the school, oblige the English boy to take part in the school games. Owing to the combined influence of tradition, public opinion, and the peculiar organization and government of the schools and universities which set the tone in

the athletic world; British interest in British sports, by reason of its universality, intensity and intelligence, stands alone. Though teachers and governing boards are sympathetic and helpful, as a rule; British athletics, as an institution, have been shaped chiefly by successive generations of boys and "Old Boys" as public-school graduates are wont to be called. The British boy has forced his masters to give him time and space for his games, — often at the expense of the course of study. It is doubtful if school and college athletics will ever be properly managed in this country, before a generation of teachers, presidents and trustees shall arise who have enjoyed the advantages of athletic training in their youth.

It is quite impossible for me to undertake to trace, within the limits at my disposal, the remarkable growth and transformation of certain sports, even in the single field occupied by the great English schools; or to note the influences which have served to intensify and spread the revival in athletics, which had its beginnings just after the close of the Crimean War and at the inception of the Volunteer movement in 1860; or to account for the changes due to the leaps and bounds with which athletics have advanced and are still advancing in England and Scotland. Even, to attempt to convey an idea of the extent to which boys and men of all classes engage in the three great British games of foot-ball, cricket and rowing, not to speak of lawn-tennis, hare-and-hounds, bicycling and the sports technically known as track-athletics; or of the amount of money contributed by the favored classes, in order to provide the sons of toil, as well as themselves, with play-grounds, swimming-baths, and gymnasias, would take me too far afield. I must content myself, therefore, with directing your attention to the fact that many of the sports now in vogue were considered vulgar and were played but little, even by school-boys a century ago; that strength and endurance rather than skill and address are the qualities most prized and worked for; that British sports are eminently social and are less marked by class distinctions than formerly; and that more interest is shown in contests between teams and clubs than in matches between individuals.

Demeny, a French physiologist, and a member of the commission appointed by his government to devise a rational code of gymnastics for use in the schools of France, urges most forcibly that athletic sports do not and cannot constitute a complete physical education. I hold this to be true of British, as of all athletics; but Demeny's further statement, that, "Games and sports are still what they always have been — an elegant means of amusement, an agreeable form of exercise, the privilege of the easy class, the pleasure of the smallest number," seems to me less applicable to the sports and games of Britain than to those of every other country. Indeed, the scope of all forms of modern physical training is wider and more truly popular than was the case in either feudal or ancient times, inasmuch as members of the privileged classes only were allowed to take part in the Grecian games or the brilliant mimic warfare of the mediæval tournaments. The sports of the Roman arena, in which the contestants were mostly slaves or prisoners of war, do not constitute a real exception to this statement, since the Roman gladiators and athletes were, like our baseball players and circus acrobats, mere professionals whose function was to amuse the populace.

Team-matches and class exercises are distinctly

modern inventions; the prizes in most forms of ante-modern contests being adjudged to individual victors. There were, to be sure, certain games among Grecian youth in which "sides" strove with each other; and, in the knightly tournaments, squadron charged squadron in the lists; but these, like the ancient foot-ball and hockey games, in which parish fought against parish, were rather mass than team contests, since the sides were at best only rudely organized, and there was little or no division of labor among the contestants. Team athletics, I repeat, have reached their highest development in cricket, base-ball, foot-ball and rowing, in comparison with which the class exercises of the Swedes and Germans, which oftentimes involve the simultaneous action of large numbers of persons, are unspecialized.

As regards length of days, British sports come next to the Grecian games, even if we do not venture, as does Hodgetts, to date them from the games of the Aesir in Valhalla. The tournaments and jousts of the Middle Age lasted scarcely 400 years; German turning took its rise in the last quarter of the last century; Swedish gymnastics have not reached their ninetieth birthday; but the history of the Grecian games extends over nearly 1400 years, from the days of Homer, if there were a Homer, till 394 A. D., the date assigned to the last celebration of the Olympic games.

In the breadth and sanity of its aims; in the magnitude of its proportions and the completeness of its development, as a national institution; in the perfection of its organization; in the splendor and solemnity of its festivals; in its many-sided and abiding influence; as well as in the length of its history and the brilliancy of its record, the physical training of the Greeks has no parallel. Its history forms a coherent whole, presenting well-marked phases of growth, culmination and decay, and reflects at every stage the spirit of the nation. Athletic contests entered into the worship of Greek gods and heroes; and the lapse of time was reckoned in Olympiads to mark the recurrence of the principal sacred games. Gymnastics were assigned an enlarged and honorable place in the training, for peace and war, of every free-born boy and youth. The codes of Lycurgus and Solon provided for the organization and regulation of bodily training, and the management of it, during its best estate, afforded positions of honor and emolument to distinguished and ambitious men. It furnished themes for poets, philosophers and historians; sculptors and painters sought the palaestra and gymnasium for their fairest models; and even the greatest of Greek physicians thought it no condescension to study and adopt exercises and procedures which had been originated by paidotribes and gymnasts.

(To be continued.)

THE efforts of the Rhode Island Board of Agriculture to stamp out tuberculosis in the dairy herds of that State are made under the authority of a statute recently enacted, which provides that the State shall pay for animals condemned and killed. This provision encourages the farmers to point out the tuberculous cows in their herds for the information of the board. Thus far the board has killed fifteen cows, and thirty-four more are in quarantine and under observation. Diseased animals have been found in four or five towns, and milk from the herds in which they were discovered has been sold in Providence.

### NOTES ON THE EXPERIENCE OF PHYSICIANS IN BOSTON AS REGARDS THE QUESTION OF OÖPHORECTOMY FOR NERVOUS SYMPTOMS.<sup>1</sup>

BY JAMES JACKSON PUTNAM, M.D.

As the problems suggested by the question before us are mainly clinical, I have thought that the best contribution I could make, would be by collecting the unpublished cases occurring in the practice of Boston surgeons, and indicating their opinions so far as possible.

With this intention I sent around a circular asking for cases of oöphorectomy done principally on account of general nervous symptoms.

If the circular had been more liberally worded it might have called out a larger number of cases, but the fact that the great majority of the gynecologists of the city answered that they had had no experience of the sort indicated, is of decided interest as showing the general estimation in which the profession in Boston holds the operation for the removal of normal ovaries on account of nervous symptoms, or even of diseased ovaries, except in response to distinct local indications.

It is certainly true that with our increased and increasing knowledge of neurasthenia and allied nervous states and their treatment, there has grown up a distrust of the theory of specific reflex causes and of royal roads to cure, a distrust well indicated by the approval with which Dr. Goodell's widely-read paper of two years ago was received.<sup>2</sup>

But we should not for the sake of the greater overlook the less. The conservative view seems to be the one which it is important to press upon general acceptance, but we should not forget the facts that make for the other side, and the group of cases here collected furnish some of these facts. It seemed to me a lack in Dr. Goodell's paper, that he did not sufficiently recognize that the causes of neurasthenia are apt to be multiple, and that peripheral irritations, though rarely the chief cause, may count for a good deal.

It is not always possible to estimate the share that a peripheral irritation has in making neurasthenic tendencies manifest; it is not always possible to treat the case under the general conditions necessary for success; finally there are nervous systems which are not easily reached by other treatment, but can be given a new tone by some striking influence. Perhaps for some of these, hypnotism or some other form of treatment by suggestion would do as much good as oöphorectomy. In two of Dr. Johnson's cases, for example, the patient improved a good deal, though only a mock operation was done.<sup>3</sup> But the physician must use his most conscientious and enlightened judgment in each case, not forgetting that each patient stands for herself and not for an average.

Finally, we should not permit ourselves to be too much controlled by sentimental considerations in deal-

<sup>2</sup> Medical News, 1889, vol. IV.

<sup>3</sup> Compare "The Curative Effect of Operations, per se" by J. W. White, *Annals of Surgery*, August, 1891. One of Dr. Johnson's two patients was informed that the operation had not been completed, and yet the favorable result occurred.

ing with the question of "unsexing" the patient. The function of child-bearing is not the only or most sacred function of every woman.

I have reports of twenty-six cases of oöphorectomy. Eleven of them were contributed by Dr. F. W. Johnson; eight by Dr. John Homans; five by Dr. J. W. Elliot, two of the latter being also under my care; one by Dr. E. W. Cushing; and one by Dr. J. R. Barss. Three of these had been published, but are reported again on account of later histories. Eleven of the patients appeared to have been benefited by the operation; thirteen were not benefited;<sup>4</sup> two died of some other cause rather too soon to make it worth while to include their cases.

This proportion of eleven favorable to thirteen unfavorable cases is, of course, of no statistical value, for we all know of cases enough where ovariectomy has been done in patients where nervous symptoms were present, though not on account of these nervous symptoms and without benefiting them.

Unfavorable results of serious character followed the operation in three cases, although in a number of others the nervous symptoms were temporarily worse, or symptoms like those frequently attending the menopause were induced. Of the three unfavorable results, two consisted in maniacal outbreaks of temporary duration, and one in an increase in the number of epileptic attacks. The operation in this case, however, was done only four months ago.

Dr. A. T. Cabot has told me of two other cases occurring in his practice where ovariectomy, which was not done for the sake of nervous symptoms, was followed, in one case by melancholia of many months' duration, and in the other by a shorter attack of mania, which ended in death on the third day. In this case the patient had shown delusions and other mental symptoms before the operation.

As such conditions occasionally follow other operations, though especially those on the genital tract, it would be hardly fair to attribute them to the loss of the ovaries in itself.

In three other cases of the group here presented, insanity came on a longer or a shorter time after the operation. It was, however, afterward learned, that mental symptoms had been present before the operation in every case.

In one of Dr. Homans's cases adhesions within the peritoneal cavity, consecutive to the operation, seemed to be the cause of considerable pain, which was increased by walking. After about a year the patient had a sudden sensation as of something giving way, and after the soreness subsided she was able to walk better.

In all the cases except one there were some signs or symptoms to call attention to the pelvic organs, and yet no such condition was present there as would have furnished sufficient surgical reason for operation.

The symptoms of chief importance were either of neurosthenic or hysterical character, or consisted in dysmenorrhea and local pains,—local, but probably on a basis of the irritable weakness that we call neu-

rasthenia. In three cases the treatment of uterine displacement, which had been previously impracticable, was made possible by the operation on the ovaries.

The majority of the ovaries and tubes were either perfectly healthy, although the nucleus for a certain amount of peritonitis, generally with adhesions, or they were somewhat enlarged, or more dense than usual, or the seat of retention cysts or dilated follicles, conditions liable, perhaps, to give rise to pain at menstrual periods,<sup>5</sup> but not likely to be important causes of serious symptoms except in the presence of a neurotic taint.

In some of the cases of this class it seemed almost certainly the bringing on of the menopause which induced the favorable result. It is this view which has been held to afford a justification for the occasional removal of ovaries which would be called strictly normal; and objectionable as it is to do this, if they are still capable of producing ova, yet it cannot be stigmatized as being absolutely unjustifiable or incapable of having a good effect.

The eight cases in which well-marked improvement occurred were briefly as follows. It should be said that the operation in one of them was done only six months ago, and in another only ten months ago, so that in these cases, and possibly in some of the others, the nervous derangement, hitherto latent, may reassert itself.

CASE I. This was the case of a young woman of eighteen, the youngest on the list. The operation was done by Dr. Homans, and the case—a very important one—has been reported both by him<sup>6</sup> and Dr. Goldsmith.<sup>7</sup> I should not refer to it here but for the fact that Dr. Homans has kindly given me new information, which brings the history up to seven years after the operation, at which time the patient died suddenly with intense pain in the head and convulsions, having remained well until then.

It was a case of so-called moral insanity of eleven years' standing, with outbreaks, especially at the menstrual period, of extreme violence. She was intelligent, but at times utterly uncontrollable and had been the inmate of several asylums, in one or another of which she seemed likely to spend her life. The improvement after the operation was so great that she went home to live, and after a time was able to support herself, which she continued to do until her death.

Dr. Johnson has also operated on a patient of eighteen, one of twins, with undeveloped uterus, who was neurosthenic and childlike. I do not count this case on the positive side, because the improvement did not begin for three years, though there are several reasons for attributing it to the operation, but the case is of interest because the patient developed physically and mentally, and from being childlike in appearance, manner and interest became more womanly and mature. There was a marked gain in flesh, as often occurs.

CASE II (Dr. Johnson). Single, thirty one years old. Symptoms: Dysmenorrhea; pain in left ovarian re-

<sup>4</sup> Since this was written Dr. J. W. Elliot has given me a later and more favorable report on a previously classified as unbenefited. The patient was a woman of about thirty, of strongly neurotic and uncontrolled temperament. She had suffered much from dysmenorrhea and retroversion, and from pains of every sort, and had become demoralized by morphine. A private letter of the date of December 4, 1894, says, "The patient upon whom you operated gained a little during the first six months. Thereafter she lost somewhat in a general way, but for the last ten months has been as well as any body. She is said to walk, eat and sleep well, and to grow stout."

<sup>5</sup> *Case Hundred Laporotomies for Various Diseases*. Boston, 1887.  
<sup>6</sup> *A Case of Moral Insanity*. American Journal of Insanity, October, 1883.

gion, generally of burning character; constipation; increased frequency of micturition; general neurasthenic condition.

Physical diagnosis: Retroflexion, with disease of left ovary and tube.

Family and personal history: There had been phthisis and insanity in the family, and the patient herself had suffered from hip-disease from her seventh to her eleventh year.

Operation, November, 1887: removal of left ovary and tube, both of which were adherent. The right ovary was left behind, although it seemed larger than normal.

Pathological examination (Dr. W. F. Whitney): Chronic peritonitis, but the tube and ovary substantially normal.

Subsequent history: Gradual but important gain as regards nervous symptoms. A year and a half ago the patient married, and has had a child. She is now doing well in every respect, and has gained forty or fifty pounds in weight. The pain and head symptoms were relieved.

CASE III (Dr. Johnson). Single, twenty-nine years old.

Symptoms: Severe dysmenorrhœa for three years past with general nervous exhaustion. When seen by Dr. Johnson she had headaches, pain in the back, morning fatigue, constipation and other signs of nervous weakness. She had attacks of hystero-epileptic character in which she would lose the use of her lips, and had lost consciousness, each attack being followed by prostration of three days' duration. The family history showed that phthisis had been prevalent, and that there had also been family worries.

Operation, January 31, 1888: Removal of both ovaries and tubes.

Pathological diagnosis (Dr. W. F. Whitney): Thickening of the peritoneal sheath, with retention cysts, and dropsical condition of numerous follicles.

Result: After the operation, symptoms of maniacal excitement. The hystero-epileptic attacks have never returned. Finally, gradual improvement. After two years the patient was able to return to work. On the whole, there has been great improvement, but not complete recovery. The patient has not been heard from of late.

CASE IV (Dr. Johnson). Single, thirty-eight years old.

Symptoms: Four years ago nervous prostration; never very strong; a school-teacher by profession. She came to Dr. Johnson complaining of intense pain in the left leg and thigh, shooting up from the sole of the foot the whole length of the leg and thigh, the pain being increased by coughing and laughing, also by a movement of the bowels; very neurasthenic; very constipated.

Physical diagnosis: Retroversion, with probable affection of the left tube and ovary. Every sort of treatment was thoroughly tried from July, 1887, to November, 1887, without improvement. Was seen in consultation by Dr. S. G. Webber, who recommended operation, which was done.

Operation, November 23, 1887: Both ovaries and tubes removed.

Pathological diagnosis: Chronic peritonitis, but tube and ovaries healthy. After the operation the uterus stayed in its proper position.

Subsequent history: April 15, 1888, the patient re-

ported by letter that she was getting on very nicely, and only suffered from general nervousness. Her spirits, which had been very much depressed before the operation, had greatly improved. Somewhat later she wrote that she was constantly gay and lively. She gained thirty pounds in weight in five months. On June 23d. of the same year, the sciatic pain was reported as still present (felt in the sacral region and running down the leg, but only when standing). Since then she has reported that she has completely recovered, and has gone back to teaching school. Would not be known for the same person.

CASE V (Dr. Johnson). Married, twenty-six years old.

Symptoms: Intense headaches of neurasthenic character, with some other neurasthenic symptoms, and dragging sensation about the pelvis.

Family and personal history: Phthisical tendencies; father extremely nervous. The patient had had headaches even as a child, had been married four years, and had two children.

Physical diagnosis: Retroflexion, and small fibroid in the posterior wall of uterus; laceration of cervix; ruptured perineum. She had had an operation for the cervix and perineum, at Denver, but found only temporary relief, and no relief from the headaches. Dr. Johnson had her eyes and pharynx thoroughly examined and treated, as possible causes of the headaches. There was some improvement, but the symptoms soon returned. She had her teeth pulled, without relief. Was seen in consultation by Dr. S. G. Webber. The retroflexion was overcome by packing, which relieved the backache so that she was able to walk without pain.

Operation, finally, on the twelfth of November, 1890. Both ovaries and tubes were removed.

Pathological diagnosis: Tubes normal, and ovaries practically so (Dr. W. F. Whitney).

Results: At first she lost ground in all respects. The headaches and backaches increased; she lost flesh and strength. Her husband became frightened, and thought she would go insane; but in three or four weeks she began to improve, and now she is better in every respect and is able to ride a bicycle.

CASE VI (Dr. Johnson). Single, twenty-seven years old.

Symptoms: A neurotic patient, Jewish by race, and of a neurotic family. She was a brilliant person, but had suffered from migraine since childhood, as her mother had before her. She was a good student. The headaches increased in frequency, and finally were of almost daily occurrence. Dysmenorrhœa was so bad that an immense amount of morphia was used from time to time, and insanity was feared. Dr. Myles Standish examined her eyes, and found insufficiency of some of the ocular muscles, and operated, securing relief for two weeks only. She was then seen in consultation by Dr. W. N. Bullard, who advised removal of tubes and ovaries. The only physical sign of consequence was tenderness in the neighborhood of the left ovary.

Operation, April, 1891: Left tube and ovary adherent. Both tubes and ovaries removed.

Pathological diagnosis: "Very little found that could be called pathological" (Dr. W. F. Whitney).

Results: The night after the operation the patient had a hystero-epileptic attack with opisthotonos, lasting for six hours. Six weeks later she wrote: "I am

feeling very well, only two or three headaches, and these lasted only a day and a night. This is such a change from the headaches of six days' duration that I am much pleased. I have gained rapidly, and am much stronger than I expected to be at the end of six months.\* The local symptoms in this case were very slight.

The patient was last seen by Dr. Johnson on October 28th, six months after the operation. She had then gained nine pounds in weight, walked three miles a day, and had had no return of the hystero-epilepsy. She has a sick headache once a week, which is relieved by phenacetine, but the former attacks of pain in the head recurred only five times. Her general health is better.

CASE VII (Dr. Homan). Mrs. S., thirty-five, one child.

Symptoms: Pain in the left side of pelvis, offensive discharge. The patient was pale and worn-looking. She had nervous prostration when eighteen, and got into the morphia habit. One ovary prolapsed and tender.

Operation, June 23, 1889: Ovaries somewhat atrophied, but otherwise normal.

Result: Marked gain in flesh and strength and general tone. Menstruation continued, and became more frequent. She gave up the morphia habit.

CASE VIII (Drs. J. J. Putnam and J. W. Elliot).

Miss P., thirty years old. Health delicate since childhood; for two years constant headaches; sleeplessness, with bad dreams; sense of weariness, and aching of the limbs and whole body; very readily fatigued; dysmenorrhoea and irritability of the bladder. The patient's sister is moderately neurasthenic.

Physical diagnosis: Uterus enlarged, retroverted and tender; ovaries enlarged, tender and prolapsed. Every means of improving the general vigor was tried that the patient's means permitted; and as the uterine condition was a source of great distress, careful, but unavailing, attempts were made to correct this also. Finally, in April, 1885, both ovaries and tubes were removed by Dr. Elliot. The ovaries were enlarged and very hard, and were pronounced by Dr. W. W. Gannett to show signs of commencing cystomata.

Result: Continuation of the headache for three months or more, after which gradual improvement. The same may be said of the other symptoms. No return of the menses. Patient, who had been dragging herself about in great distress for nearly two years, returned to work six months after the operation; and although she has been obliged to be careful, she has improved steadily ever since, and says that she was never in such comfortable condition as since the operation. She has worked regularly and with pleasure, and supports herself. The result has been in every respect satisfactory.

CASE IX. Dr. E. W. Cushing<sup>6</sup> has reported a case of dysmenorrhoea, confirmed masturbation and melancholia, in a negress, with excellent results, which have persisted. Dr. Cushing has kindly written to me the following, under the date of October 10, 1891; for which reason I report the case here.

The ovaries, it may be said, were reported as somewhat enlarged, and one of them contained a cyst.

\*In regard to the patient of whom you inquire, I am pleased to be able to state that the operation was com-

pletely justified by the results. The melancholia disappeared immediately after the operation. For several months the patient remained rather feeble, owing to her great emaciation and generally shattered condition, then she began to work as a seamstress, and later was able to do kitchen work; something over a year after the operation she came to me to know whether she might properly marry. I found that the proposed husband was a widower with several children, and that the nature of her operation had been explained to him, I therefore saw no impediment to her marriage, which accordingly took place; at last advice she was living very happily in New Brunswick, taking care of her household and her adopted children. I may add that, while the operation seemed to relieve both the melancholia and the desire for, and practice of, masturbation, it did not abolish the natural sexual feeling. In a large number of cases where the ovaries and tubes had been removed from adult women, I have never found one who felt that the operation had in any way impaired her sexual capacity or diminished what sexual desire she had had before the operation.

CASE X (Drs. C. P. Putnam and J. W. Elliot). Single, about thirty years of age. General health poor: old-blip-disease, with persistent deformity; severe dysmenorrhoea, with headaches and backache, and symptoms of excessive nervous weakness, which prevented all effort. There was no other evidence of pelvic disease, and the operation was undertaken in the hope of improving her health by relieving the dysmenorrhoea,<sup>9</sup> all other feasible means having been used without success. Both ovaries were removed, although healthy, on September 20, 1890.

The patient was seen by me, October 20, 1891, and reported as follows: "She has less headache, and is very much less nervous, and, on the whole, she feels much more natural and better. Her strength is feeble and she still sleeps poorly, but this has always been the case. Up to last September she continued to have severe abdominal pains, though not constantly, coming on especially after fatigue, and occasionally shooting down the thigh. In August she had one of these attacks, but none since then. 'Hot flashes' have occurred ever since the operation, especially after fatigue. She has not been able to work much since the operation, on account of lack of strength; but on the whole, she can do more than before, and is not hindered from working by general nervousness. There has been no return of catamenia."

CASE XI. I can report the result at the end of five years, in an interesting case operated on by Dr. J. Richmond Barrs, of Malden, under whose care the patient had previously been, and communicated by Dr. G. L. Walton to the American Neurological Association on June 20, 1884,<sup>10</sup> six months after the operation.

In brief, the case was that of a single woman, twenty-nine years old, without neurotic inheritance. She had suffered ever since puberty with dysmenorrhoea and backache. For two years she had been confined to the house, and for a good part of one year to her bed. She had become excessively weak and nervous, and was subject to frequently recurring convulsive attacks without either loss of consciousness or the usual signs of typical hystero-epileptic seizures.

Dr. Walton, who was called in consultation, found a well-marked hemi-anesthesia, and signs of extreme irritable weakness of the nervous centres, besides great

<sup>6</sup> There was not undertaken to collect all the cases where dysmenorrhoea furnished the sole reason for the operation. A number of such cases have occurred.

<sup>9</sup> Journal of Nervous and Mental Disease, vol. xi, July, 1884.

<sup>10</sup> Journal American Medical Association, Chicago, 1887.

ovarian tenderness. The ovaries were found full of small cysts,<sup>11</sup> but not materially enlarged.

Dr. Barss writes, under the date of October 20, 1891: "In 1889, five years after operation, she was remarkably well for her, and was earning her living at sewing, could walk quite good distances. Previous to the operation she was practically confined to the house for two years, one of which was mostly spent in bed. Her tubes were not removed, and she flowed for several months more than she ever did before. I should say it was a year before we began to see marked improvement. To my mind her case was very satisfactory."

Besides these hitherto unpublished cases, Dr. Homans has recorded four,<sup>12</sup> in none of which material or permanent improvement occurred.

Dr. Elliot suggests one reason for doing oöphorectomy, which is, of course, familiar to gynecologists, but not so much so to the general practitioner; that is, that, by inducing the menopause and uterine involution, it may secure the disappearance of painful and wearing uterine affections not to be treated successfully in any other way, without inducing an amount of fatigue and depression which in the case of many debilitated and neurasthenic patients, would overbalance the benefit received. Of course, in many such cases a thorough treatment of the underlying nervous state might render gynecological treatment unnecessary.

Finally, I have a case of male castration to report. The patient was not under my care when the operation was done, but the case has never, to my knowledge, been published.

The patient is now a man of forty-one. He has been unbalanced all his life, and especially so since a severe blow on the head in childhood. The operation was performed three years ago. For some years previous he had been a dipsomaniac, and excessively and openly erotic; and for a time it had been necessary to confine him in an asylum.

The castration was done at his own urgent desire. His friends confirm the statement that he makes, that his mental condition improved to a marked extent. He is at present unreliable and suspicious to a considerable degree; but his desire for liquor and his erotic tendencies have been absent since the operation, and his disposition has been quieter, so that he is able to live alone and take care of himself, though requiring more or less supervision.

In conclusion, I do not claim that the favorable results reported for these cases could not have been brought about in some other manner, but only that they were, or seem to have been, brought about in the way described, and that the patients are not reported as regretting the operation.

The following opinion seems to me the most reasonable:

When ovarian or uterine disease of slight or moderate amount is associated with marked nervous symptoms, whether these are of the nature of unusual local pain or of a more general character, it is rarely the case that the local disease is alone at fault, and the physician should look carefully for other signs of the main trouble in the nervous system itself. It is so often found, in practice, that by invigorating the gen-

eral nervous condition the patient can be made comparatively insensitive to local irritations, that, before deciding on a step which may lead to bitter regret and disappointment, or to more or less persistent nervous symptoms of the former, or of a new type, the physician should omit no other means for accomplishing his aim, which study, determination and skill can secure; and even if he fails he should remember that his chance of success through oöphorectomy is not of the best. It should be especially borne in mind that the elements of personal temperament and personal influence play an important part in the treatment of neurasthenia and mental disorders, so that some new physician may succeed where many have failed, or that every one may do better than he believed possible, if he chooses the best method and relies upon it with sufficient persistence. It is certainly true that neither the patient nor the physician is likely to devote the necessary determination and zeal to the general treatment, if the possibility of a more speedy cure by operation is kept looming in the background. In the minds of both of them the treatment selected should be for the time the only treatment.

"When half-gods go, the gods arrive."

The new light which the investigations into hypnotism and kindred subjects have thrown upon the pathology and therapeutics of the nervous system, indicate that when oöphorectomy cures neurasthenia, it sometimes does so by so-called "suggestion," that is, by influencing cerebral processes not ordinarily concerned in active consciousness,<sup>13</sup> but having a great deal to do with the nutrition, sensitiveness to pain, and the like, and there is always room for hope that some other and less objectionable means can be found of exerting this influence. It is probable that electricity and the "rest-cure," as well as hypnotism, act often in this way.

All this the physician should conscientiously say to himself, but, having done so, he should with equal conscientiousness recall the cases in which oöphorectomy was the agent that restored the wished for health, and should look upon it as another and valuable string to his bow, though one of only occasional utility.

As regards the kind of cases in which oöphorectomy seems most justifiable — apart from considerations of non-medical character — it is doubtless true that the serious, typical neuroses, and especially epilepsy, are rarely benefited, and the less so in proportion as the symptoms are of definite character and independent in origin of the pelvic disease. The mere fact that nervous symptoms are worse at or near the time the menstrual period, by no means necessitates the conclusion that there is any important causal connection between the two series of events.

On the other hand, it would be incorrect to conclude that because a woman has neurasthenia or hysteria, even if they be on an hereditary basis, and wholly independent in origin of pelvic irritation, it is therefore impossible that the removal of such irritation, or the induction of a premature menopause, could be a means of cure. This may not happen often, but such cases as Case I of this series, shows that it does happen occasionally.

THE German Government is to establish a modern, well equipped biologic station on Heligoland.

<sup>11</sup> See the opinion quoted from Dr. Whitney above as to the relation between cysts and dysmenorrhea, *Laparotomies*, Boston, 1887.

**REPORT OF A CASE OF HÆMORRHAGIC OVARIAN DISEASE, WITH LAPAROTOMY FOR INTERNAL HÆMORRHAGE; DOUBLE OVARIOTOMY; RECOVERY.<sup>1</sup>**

BY GEORGE W. DAVIS, M.D., HOLYOKE, MASS.

I wish to premise the report of this case very briefly by saying, death from internal hæmorrhage is of more frequent occurrence than is usually supposed. Internal hæmorrhage, even of severe type, is in some of its varied forms liable to go unrecognized, the symptoms accompanying it being attributed to other sources, or, if recognized, its importance may be under-estimated; medicines and general management being relied upon for its control when nothing short of opening the abdomen and securing the bleeding vessels can save the dying patient. These cases are often urgent, allowing no time to secure a special operator from a distance. They are, in fact, frequently emergency cases. Valuable time should not be wasted in useless consultation with physicians who never operate, consequently seldom appreciate its importance, and when the question of operation arises, are almost sure to decide against it.

I have to record three cases occurring during my experience, where the patient died from internal hæmorrhage, and in each of these cases I was able to secure a post-mortem examination which confirmed my diagnosis and convinced me that a laparotomy might have saved the patient. Is it probable that such cases would occur more frequently in my practice than in that of my neighbor?

My reflections upon these deaths together with others where no post-mortem was possible, with such study of the literature of internal hæmorrhage as I have been able to make, have led me to make many resolutions and some preparation for the future management of similar cases.

I was called July 20, 1891, by telephone, to Westfield, to see Mrs. B., in consultation with Dr. E. B. Karner. Upon my arrival I met Dr. E. D. Hutchinson, who had been previously called, and who was now in attendance with Dr. Karner. From these gentlemen I learned the following history of the patient. Age thirty-three, married thirteen years. Never had children, and had never been pregnant to her knowledge. At the time of her first menstruation, which occurred when she was aged sixteen, she was caught out in a severe winter storm, and walking a long distance became nearly frozen. Menstruation had always been irregular. She had a nervous temperament with hysterical tendency, and two years ago, showed indications of angina pectoris by several painful attacks.

May 25, 1891, she commenced flowing, but had no pain, and was about the house till June 18th, when she was taken with severe pain in left side of bowels, which she thought was another attack of angina. Four or five days later, Drs. Karner and Hutchinson found, by vaginal and external examination, a solid movable tumor in the left pelvic region. The pain and tenderness gradually subsided, but the tumor continued to grow larger while its solidity became less marked until July 19th, at bed-time, when she was seized with severe pain, and Dr. Karner was called. He found her nearly unconscious, blanched, nearly pulseless, with irregular and jerky respiration. The doctor con-

sidered her condition alarming — liable to die at any moment; but with suitable restoratives she rallied, and was seen next morning by Dr. Hutchinson, who confirmed the report of her condition just stated. Dr. Karner had recently seen something in the lochia which resembled placental tissue, but further than this there were no signs of pregnancy. The abdominal enlargement was now rapidly increasing, and tenderness had become extreme. The pulse was getting weaker and more rapid. Elevation of temperature had been present. I found the patient at 6 p.m., very weak, with an anxious expression which indicated she was suffering from something of a serious nature. She presented a sallow complexion suggestive of blood-absorption. Upon examination the abdomen was found considerably distended and extremely sensitive; so much so, as to preclude the desirability of percussion, but by light and careful palpation I made out the enlargement in abdomen which was most prominent in the left iliac fossa; but the abdomen was more generally distended, and I could satisfy myself of the presence of some larger mass above and extending to the right of uterus. Upon vaginal examination the posterior cul-de-sac was found to be obliterated by a semi-solid mass which filled the pelvic cavity pushing the uterus before it, the cervix being pressed against the symphysis, was difficult to recognize in its new position, and surrounded by the tense abnormal swelling.

I was able, however, to satisfy myself by bimanual examination, that the uterus was not much enlarged and that the mass above as well as below was not very intimately connected with it.

My diagnosis was internal hæmorrhage, making a hæmatocoele or hæmatoma on left side, with peritonitis developing, and possibly if not probably, extra-uterine pregnancy, and, with ordinary treatment, the prognosis was unfavorable; she could not survive many days and the bleeding might at any time become more profuse, and end the patient's life abruptly. I believed surgical interference might give her a chance for recovery, while without it she had none. Upon being questioned I said she would have one chance in two to recover if she selected operation. After consulting together the family decided for operation, and I was requested by the attending physicians to operate. I promised to return on the next day and make the operation.

In the meantime the adjoining room which was used as a family sitting-room, was converted into an operating-room by removing the carpet and furniture, giving it a thorough sweeping and cleansing, and thoroughly airing it by leaving the doors and windows open.

The patient was bathed, rectal enema and vaginal douche given. This patient was treated in her own home, which was in the lower story of a tenement building, where the surroundings, from a sanitary point of view, were much neglected. The patient's room was connected with the family kitchen. She occupied the same bed after the operation that she had previously used, and while all persons connected in any way with the case were quite anxious to add to the patient's comfort and safety, many things were from necessity not as we would have desired. A new tin wash-boiler was secured, filled with water, and heated on the kitchen stove, also several new milk-pans for the sponges and instruments. Several large

<sup>1</sup> Read before the Massachusetts Medical Society, Hampden District, October 20, 1891.

pitchers were filled with the various solutions to be used, and marked, so no mistake could occur. A fountain irrigator was arranged, but we found that too much time was consumed by its use and it was discarded. At 4 p. m., July 21st, the patient having been etherized, mons veneris shaved, and the abdomen thoroughly washed in soap and water and sublimate solution followed by application of ether, the lower abdomen surrounding the seat of operation being protected by warm towels wet in sublimate solution, the operation was commenced.

There were present and assisting, Dr. E. B. Karner, Dr. E. D. Hutchinson of Westfield, Dr. Ella M. Davis of Holyoke, and the nurse Mrs. Clark of Springfield. Upon entering the abdomen in median line and introducing two fingers to explore its cavity, almost at once I opened up a large hæmatocele at the left, from which black and grumous blood flowed out, filling the wound and flowing over the patient.

This was caught with sponges, towels, etc., for the moment, and Tait's trocar was introduced into this blood cavity as soon as possible, and a portion of its contents drawn off, but as there were many clots the trocar was soon clogged with them and rendered useless. I then tried to remove more of the cavity contents with my hands, but found it impossible to do so, as the brim of the pelvis was so completely filled by a large cyst which rendered its entrance from above impossible. This proved to be a multilocular cyst of the right side. The abdominal wound was now enlarged, and this tumor reduced in size by tapping and the use of trocar until I was able to lift it out of the abdomen. There was almost no pedicle. It seemed to spring from the right side of the uterus. This was, after some difficulty, ligated as close to the uterus as possible and cut off with scissors. A Staffordshire knot was used; but owing to the great amount of tissue included in the ligature I feared it might not remain secure, and tied the mass again in two parts, leaving the three silk ligatures in and surrounding the stump. In tying the Staffordshire knot the ligature broke twice, although I had tested it a few hours before with my full strength and could not break it.

All this had taken time, the patient was getting weak, and I was notified that the pulse was failing. The hæmatocele was now cleared out with my hand and with sponges, the intestines being held back and kept covered with warm towels wet with sublimate solution. The hæmorrhage now became quite active in the blood cavity, and I introduced my hand and found an irregular mass, quite firm, which was also the source of the hæmorrhage. It was quickly separated from the surrounding tissues by the hand only, guided by the sense of touch. It was actually torn from its bed in the mass of deposit with which it was surrounded. The adhesions were very firm, and I feared the underlying structures would be injured, but there was no time to lose, as the patient's pulse had stopped, and we thought she would die on the table. This mass, which included the left ovary and tube with a cystic and hæmorrhagic tumor which had ruptured, was quickly tied off and cut from the pedicle. Then as quickly as possible the pelvic cavity and lower abdominal cavity was filled with previously boiled water, its temperature several degrees above that of the body, poured in from a pitcher and thoroughly washed out. This was done several times, and certainly did much to resuscitate the patient. Hypodermic injections of brandy were also

given. The abdominal and pelvic cavities were quickly dried, the wound closed with catgut sutures, and a large and long glass drainage-tube, which reached to the bottom of the pelvic cavity, inserted. The wound was covered with borated cotton on which was spread an ointment of iodoform (one drachm), boracic acid (two drachms), bismuth subnit. (four drachms), with vaseline (two ounces), and the patient hurriedly put to bed. The bed had been supplied with hot-water bag and bottles, hot blankets, etc. Through the efforts of Drs. Karner and Hutchinson the patient soon began to show signs of recovering from the collapse in which she had so nearly died.

Evidence of general peritonitis was not found. The blood had been confined to the pelvis by the cyst of the opposite side, which effectually blocked the pelvic entrance and lifted the intestines before it into the upper abdominal cavity. The quantity of blood and clots removed from the hæmatocele was estimated by those present to be about two quarts.

It was now nearly time for the train, and I hurriedly left the patient with her former attendants. The nurse recorded the time of operation as about one hour and fifteen minutes.

The next day the temperature in the morning was 99°, evening, 100°; morning pulse 110, evening pulse 128. Patient very thirsty.

July 23d; temperature in morning 99°, evening, 100.8°; morning pulse 120, evening pulse 108. Abdomen was very tympanitic. Thirst continued. The wound was examined and drainage-tube found to be too long; it was changed for a shorter one. The discharge from wound was very slight.

July 24th; temperature in morning 100.2°, evening, 99°; morning pulse 120, evening pulse 108. The drainage-tube was removed and a stitch inserted. Several movements from the bowels with much gas, followed by relief to the patient. Thirst subsiding.

July 25th; temperature in morning 98.2°, evening, 98.2°; morning pulse 106; evening pulse 100. The bowels still remain quite tympanitic, and the patient suffers pain from this cause. Dr. Karner passed a flexible rectal tube, and succeeded in relieving the bowels of a great quantity of gas.

The tympanitis seemed to be the occasion of nearly all the complaint of the patient, and it gradually diminished from this time on. The stitches were removed on the eighth day, and the wound was in the best of condition. Except for a slight chill on the night of the eleventh day, which was caused by an open window and insufficient covering, the patient steadily improved from this date on, and sat up for the first time August 16th, twenty-six days after the operation. At the present time, which is between three or four months later, she is entirely well.

Of the two masses removed at this operation, the larger is the cyst removed from the right side. It appears modest in size, in a collapsed condition; but as it lay distended in the abdomen, it was perhaps twice the size of an adult head. It is multilocular, being divided into six or eight unequal portions. The other specimen, about the size of a man's fist, is very irregular in shape, and presents a ragged and shredly surface caused by the torn adhesions. The left ovary and tube are seen and readily recognized; this cyst is also of the multilocular variety. The rupture is plainly seen which permitted the blood after having distended the larger portion of the tumor to escape into the per-

itoneal cavity. At the time of removal, this tumor was filled with coagulated blood.

My reasons for reporting this case are:

(1) My belief that the case is of great interest as explaining the source of hemorrhage in obscure cases which may be found many times in a hemorrhagic state of diseased ovaries and appendages.

(2) It is interesting and instructive to know that a patient may endure an operation of this kind and make a good recovery after the general circulation has lost so much blood, and this in a patient who had suffered from such general constitutional disturbance, as well as from local pelvic inflammation, lasting for several weeks.

(3) This case presents a strong argument showing that patients who require laparotomy can be successfully treated in their homes with the aid of good trained nurses, whom we fortunately have at our command. Furthermore, it tends to show that the general surgeon may be competent to meet the exigencies of similar cases, and that cases of emergency should not be allowed to die by a waste of time in attempting to obtain the services of a specialist from a great distance.

### THE SEMI-PRIVATE CARE OF EPILEPTICS.<sup>1</sup>

BY LUCIUS W. BAKER, M.D.,

*Superintendent Revere Sanitarium for Nervous Invalids, Baldwinville, Mass.*

IN nearly every community will be found one or more individuals who are suffering from that peculiarly distressing disease known as epilepsy. Niemeyer places the proportion of such cases at six in every thousand.

In this disease the autopsy and the microscope have afforded us but little satisfaction. There seems to be no fixed and constant pathological lesion attendant upon the wide assemblage of symptoms classified under the name of epilepsy. The few histological changes which have been reported are, it seems to me, to be considered as results rather than causes of the disturbance.

But if our knowledge of the actual pathological changes occurring in epilepsy is vague and unsatisfactory, the results of experiment and clinical observation are more gratifying, for the researches of J. Hughlings-Jackson, Gowers and others have furnished us with a more satisfactory explanation of the phenomena of the disease than any we have heretofore possessed.

According to these observers an epileptic paroxysm is due to a sudden and excessive functional activity of the gray matter in some portion of the brain. This rapid action of certain nerve centres, with its resulting phenomena, is called a "discharge," which may commence in any part of the gray matter of the brain, remain confined to the portion in which it originated, or may extend to and involve other portions; hence the wide variety of manifestations which constitute an attack. There may be, for example, a momentary loss of consciousness, a slight incoherence, or mental blank, without muscular spasm; or the attacks may be of a convulsive character, involving few or many muscles; or the greatest variety may be present, or the pa-

tient may have no warning whatever of an approaching seizure, while not infrequently the attacks are preceded or followed by more or less mental excitement.

This rapid liberation of energy in the nervous centres, giving rise to an epileptic paroxysm, may be due either to a sudden diminution of inhibitory power, or to an excessive and rapid generation of nerve force within the cells affected. It is, however, important to remember, that the primary and essential element in the production of a "discharge" is the presence of an inherent instability of certain portions of the gray matter within the encephalon, which may be due to heredity or other predisposing causes, some of which are beyond our power of detection.

The manifestations of epilepsy are such as to usually incapacitate the individual from engaging in the ordinary occupations of life, and not infrequently compel him to become a useless burden upon his friends or upon society. In the vast majority of cases epileptic attacks leave a permanent impress upon the cerebral structure; we seldom meet with a case in which careful study will not detect some evidence of mental impairment. Many terrible crimes have been committed during an outburst of epileptic mania, while all degrees of mental degeneration will be met with down to complete idiocy or dementia.

An epileptic is not only exposed to all the dangers resulting from a sudden loss of consciousness; he may also, in a greater or less degree be mentally defective. He has, therefore, a double claim to be dealt with according to his peculiar requirements. But, singular as it may seem, when we consider the nature of his malady, these claims have, in this country at least, been almost entirely ignored.

At present the only place, to my knowledge, in which an epileptic can be received for care and treatment is in institutions devoted to the care of the insane and these are obviously unsuitable for this class of cases. Hospitals for the insane are intended only for the treatment of mental diseases. This is their special office. They were never designed for the treatment of epileptics any more than for the treatment of dipsomania, and it is a manifest injustice to send an epileptic to one of these institutions. Such a course cannot but be detrimental to both classes.

During their freedom from attacks, epileptics resent the companionship of the insane, while the latter ought never to witness the wild contortions or to hear the piercing cry of an epileptic seizure. *So far as the care which society extends to its afflicted members is concerned, a man had better be insane than an epileptic.*

I am well aware that the medical profession generally entertains a gloomy view with regard to the results of the treatment of epilepsy, and that the opinion prevails that it is an incurable disease. Granting for a moment that this is correct, is not the same equally true of many other diseases the severity of which we are able to relieve materially by judicious care?

One advantage, among others, which the long-continued hospital treatment of epilepsy will secure, is the administration of the necessary remedies with unfailing punctuality, and the proper regulation of the diet; two important factors in securing a favorable result. The difficulty of securing these necessary conditions will account for many failures in the treatment of this disease in private practice. I have frequently had patients remain entirely free from attacks during a hos-

<sup>1</sup> Read before the Section for Clinical Medicine, Pathology and Hygiene, of the Massachusetts Medical Society, Suffolk District, October 21, 1891.

pital residence of months, but have known the seizures to return soon after their removal to home surroundings.

In an interesting paper<sup>2</sup> read before this Society last December, Dr. W. N. Bullard called attention to the lack of proper facilities for the care of the pauper epileptics of Massachusetts, and urged that separate provision be made for this class of patients. The subject was quite fully discussed at the time, and at the last annual meeting of the Massachusetts Medical Society, a committee was appointed to present the matter to the Legislature. Should any action be taken by the State, I presume that certain cases of epilepsy, now in the State hospitals for the insane, will be separately provided for, as will also those cases now in institutions for children, who have reached adult life.

Several years ago I became interested in the care of epileptics in connection with a small charitable institution for children, which was then in its infancy, and which was one of the first in this country to provide special accommodations for this class of patients. At that time we received a few patients who were beyond the age of childhood, and also foresaw that a difficulty would arise within a few years as to what should be done with those who, coming under our care as children, should remain until they became adults. This is now proving a serious problem to the managers of the same institution, whose capacity has since been largely increased. Their last report says, "that of the reported number of cases of epilepsy a very large proportion is above the age of fifteen years. As a rule, parents prefer to keep their own children if possible, and while they are young it is generally possible; but after they get to larger years the difficulty of managing them becomes more than the family is willing to undertake, or the friends to permit. They are then reported as epileptic and a place of asylum is sought for them. The larger number of our applicants is of this class. The number is a growing one, and the time is near when provision must be made for the hospital care of a considerable number."

The older cases of epilepsy are manifestly out of place in an institution for children, but as yet there is no other place to which they can be sent, except the insane asylum or almshouse. As the matter of providing for adult pauper epileptics was carefully considered last December, it is not necessary for me to discuss it further at the present time. I desire rather to call your attention briefly to the desirability of also providing suitable accommodations for epileptics whose friends are able to pay a moderate sum for their support.

No one who has not had practical experience with such a patient can appreciate the continuous strain which an epileptic occasions in the family to which he belongs. The constant liability to disastrous falls or injuries, the mental hebetude, the irritability, the peevishness, the unearthly cry, the distorted features, the wild contortions are a continued source of care and anxiety which few can long endure without injury.

In the ordinary home, an epileptic can seldom obtain the care which his condition requires. The wealthy can, of course, provide separate apartments and special attendants, but even these often prefer accommodations elsewhere. I have had such cases under my care in the past, and within a few weeks I have had a most urgent request to receive an epileptic patient,

whose parents are both able and willing to pay well for his care. Similar letters come to me from time to time showing that there is a demand for such accommodations even among those who are amply able to care for their friends at home.

But the burden rests heavily upon those in moderate circumstances, whose means will not permit their entrance into a strictly private institution even if they could be received. Such cases are willing to pay all, and even more than they are able.

I doubt not but that there are many cases of epilepsy among the middle classes of this State, who for their own and others' sake ought to be taken care of away from home, but whose friends will not allow their removal to any strictly charitable institution for epileptics, did one exist.

The scale of expenditure demanded in the private asylums is such as to place them beyond the reach of people of moderate means, and even those whose circumstances will enable them to command the resources of these institutions are debarred from entering them on account of the nature of their disease, for epileptics ought not to be associated with nervous or mental cases, in the same institution, or even within the same grounds. I speak from experience, as I once had a cottage filled with mild private cases of epilepsy, but was obliged to send them all away, on account of its close proximity to another building in which there were other nervous patients.

It seems desirable, therefore, that these cases should be provided with suitable accommodations away from other patients, and at a sufficient distance to prevent annoyance to the community in which they may be placed. The buildings should be arranged with special reference to the peculiar requirements of those who are to occupy them. A one-story structure will be preferable, and the house and its furnishings should be constructed so as to diminish, as far as possible, the liability to injury from falls.

I can see no serious obstacle to the establishment and maintenance by benevolent people of small institutions for the care and treatment of non-pauper epileptics. Such an establishment in my opinion should be entirely free from State control. It should be managed by a board of trustees as a private institution, with nothing in its name to characterize its special work.

The building should be located in the midst of ample grounds, without neighbors in its immediate vicinity, and provision might well be made for a variety of light occupations, as during the intervals between the attacks many epileptics are able to work, and are much better for being occupied. The house should also be furnished with all the comforts to be found in the homes of people of moderate means, so that the home-like atmosphere may be continued as far as possible. If suitable rooms were provided I have no doubt they would soon be occupied by those able to pay a large sum for their accommodations, thus diminishing the expenditure of the institution.

In brief, I would furnish this class of epileptics as I would many of the milder cases of insanity, with all the comforts of a well-ordered home; with trained attendance and with skilled medical care at a price within their limited means.

I am well aware from personal experience that such accommodations will be quite expensive. To carry on such an institution successfully the amount received for

<sup>2</sup> *Journal* vol. cxxix, p. 25, *Discussions*, p. 36.

board must be largely supplemented by the contributions of benevolent people able and willing to aid such an enterprise. An endowment fund will be of the first importance, and this would doubtless be secured as soon as the necessities of this class are fully understood.

It is our pride and boast that Massachusetts never turns a deaf ear to the cry of the sick and the suffering, that no worthy enterprise lacks support among us. I trust that the time is not far distant when to our long list of benevolent enterprises will be added one or more devoted exclusively to the treatment of epilepsy.

## Reports of Societies.

### MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODETT, M.D., SECRETARY.

WEDNESDAY, October 21, 1891. The meeting was called to order at 8 o'clock by the Secretary. The first business was the election of a chairman. Dr. E. G. Cutler was unanimously re-elected to that office.

Dr. L. W. BAKER, of Baldwinville, Mass., read a paper upon

#### THE CARE OF EPILEPTICS.<sup>1</sup>

MR. F. B. SANBORN, formerly Inspector of State Charities, opened the discussion:

I have been long acquainted with Dr. Baker and with his interest in this subject, the care of epileptics. I do not know whether Dr. Baker attempted to give any estimate of the number of epileptics in Massachusetts. I have never been able to arrive at any estimate. The census does not give any estimate. Within a few days, however, expecting to listen to Dr. Baker here, I endeavor to look up the matter. I went to the different boards in Boston, and I find it is not in the possession of any board or bureau in the State, and can only be arrived at by estimate. I suppose we have at present in Massachusetts not less than 8,000 insane and idiotic persons. The census may not show so large a number. Now of those two classes a definite proportion, not less than five per cent., is always found to be epileptic. I estimate, therefore, that if we have 8,000 persons mentally affected in Massachusetts, we must have from 400 to 800 epileptic persons among them, in the later stages of epilepsy, ordinarily where the mind has been seriously and oftentimes permanently affected. There must be at least double this number I suppose of persons where epilepsy has not yet reached this stage. It may never get so far. I therefore suppose that we must have in Massachusetts from 1,200 to 2,000 persons of the epileptic class. This probably is constantly increasing as our population increases.

Now the State has made no provision, separate from the care of the insane, for this class of persons, except in the small institution which Dr. Baker founded at Baldwinville, and which contains at present something like 80 epileptic children in the hospital cottages. Most of these are persons belonging to the pauper class, that is to say, come from families not able to pay even the small sum which is required in the institution

for the board of the children (amounting to about \$3.25 per week), and therefore are supported either by the State or by the gifts of benevolence. There are some supported in the almshouses, etc. There is, in addition to this class of the epileptic poor that must be supported by the tax-payers, a considerable class of persons whose friends are able to support them, but have absolutely no place to which they can be sent, where they can receive special attention apart from other patients, which epilepsy requires. That is a serious deficiency in our charitable system. It is one in which Massachusetts is not alone by any means. There is no State in the Union, I think, which maintains a special institution for epileptics which is sufficient to receive the epileptic persons of that State, and few of the countries of Europe have any such institution. There are several excellent institutions for epileptics in Europe; but in Massachusetts we certainly are able to support, and I think the munificence of individuals will be ready to organize, an institution for persons of small means, who can afford to pay the expense of placing their relatives in such an asylum. It would be necessary, I suppose, to begin in a small way and probably it would be found desirable not to increase the number of inmates of such an asylum to anything like the number treated at Bielefeld. That would be my own view of the subject. The public authorities will provide in their own manner, and they will constantly improve the treatment of their own cases. They will provide for the epileptic poor; but the other class will be compelled, until some such asylum is established, to be sent either into families where oftentimes they can be properly treated, (but by no means the whole number can be so disposed of), or else into asylums for the insane, where they not only very much disturb the treatment of the patients who properly belong there, but fail to receive the treatment which they themselves require.

The case of Barber, reported in the *American Journal of Insanity* by Dr. Wise, which came under my personal observation, illustrates well the dangerous homicidal tendencies of some epileptics.

I suppose there is hardly a person in this community who would be less suspected of epilepsy than Richard Barber was for months and years before this homicide; and yet, he being subject to a species of latent epilepsy, seizures occurring only in the night, had fallen into the dangerous and distressing condition which epilepsy sometimes produces, that is homicidal fury, which will cause an assault upon any person within reach of the epileptic. He had killed his two best friends in America, and when it was over he was unconscious of the deed.

This is one of the dangers to which any community is exposed which makes no provision for its epileptic subjects.

MRS. MARY A. LIVERMORE: While Mr. Sanborn was talking, I have been running over in my mind and trying to make a *résumé* of the number of persons I have known who have been afflicted with epilepsy in the last thirty-five years. I am able to recall forty two. The results of my observation have convinced me that this affection is much more common than one would think. I have not found that a very large proportion of epileptics are connected with the very poor people, or those whose lives have been exceedingly barren of comfort or nourishment or who have been very much vitiated by bad habits or bad methods of living. Almost all the epileptics whom I know are so situated

<sup>1</sup> See page 651 of the Journal.

that they could pay for care in an institution, if there were one in which they might be received. They could not pay fabulous prices, but could pay *something*. Of the eighty epileptics now in the hospital at Baldwinville, I am informed that forty pay *something*. So that it does not seem as if it would draw so very largely on the funds of those charitably disposed if this matter were attended to.

Everything that has been said concerning the difficulty of taking care of epileptics in the *family*, is so true that it cannot be overstated. It is not a possible thing, unless one can set apart rooms for the epileptic, and have one person in charge of him constantly. I have found that in cases where the epileptic could be absolutely under control in regard to habits of rising and retiring, food, etc., the horror of the thing could be mitigated and the person made companionable and attractive in the family. I believe the frequency of attacks may be greatly diminished by strict attention to food, habits, etc.

Mrs. Livermore described at length an institution for epileptics in London, in which the different classes of epileptics received treatment suited to their condition.

Dr. T. W. FISHER: When the subject of a new hospital is broached, the questions always arise. Where are the patients coming from? Is there a sufficient number of patients of that kind to avail themselves of the new institution? Perhaps these are not difficult questions to answer, for I do not know of any hospital so large that it could not be filled in six months.

The question of epilepsy is interesting, like everything connected with the subject. I was unable to get any facts in regard to the number of epileptics in Massachusetts; neither could I find directly the number of epileptics in our State hospitals in Massachusetts. The statistics deal with admissions only, and not with the number of resident epileptics. The number of epileptics in my own hospital, which contains 435 patients, is 27, or about six per cent., and six per cent. of the number in the State hospitals would be about 300. The number admitted to the State hospitals for eleven years I find to be 731 cases of epilepsy. In that number 17 recovered and 231 died, showing an extremely high death-rate, and an extremely light percentage of recovery. Perhaps some allowance is to be made because recovery from epilepsy is rather deceptive. The United States census for 1880 shows 71,484 insane in the United States, of which 6,812 or nine per cent. were epileptic. In 1880 I find that there were 281 epileptics in the State institutions, or six per cent. of the number of insane.

In Berlin the number of insane in the city has increased very rapidly, much more so than the population; and the number of insane in the hospitals of Berlin, public and private, in 1890 was 22,659, including idiots and imbeciles and epileptics. Of this number 494 were epileptic, showing 19 per cent. against six per cent. in this State, so that our proportion of epileptics in insane hospitals is much less. At Bielefeld, which I visited, I saw institutions for the treatment of epileptics containing 100, who are mostly pauper epileptics, and who are taken care of in a most suitable and creditable manner. I saw one immense dormitory containing nearly 100 epileptics having beds about twelve inches high, so that the person could receive no injury by falling out of bed at night. That ward was under constant surveillance during the night, and aggravated cases were at once removed to the adjoining

sick-ward. But the number of epileptics in Berlin has increased so rapidly, as well as the insane, that they are about to build a separate colony hospital for about 600 epileptics. This meeting is not especially concerned with that class of epileptics, but the statistics may be of some interest. The increase of insanity in Berlin and Germany, which is far beyond that of the population, is also the same increase as seen in the United States. In 1881 the number of insane in the United States in hospitals was fixed at 56,205, in 1889 the number was 97,534, an increase in nine years of about 75 per cent., while the population has increased 25 per cent.

There is no doubt about there being enough epileptics, of the class mentioned, in the State to fill any hospital that the benevolently inclined are likely to erect. Being connected with a public hospital, I see fewer of the cases of epilepsy of this sort, than physicians in practice outside; and I do not imagine that this new institution would make any great drafts on the State hospital or city hospital for insane. The cases that go to those hospitals are generally the long-standing cases in which the mental symptoms are very pronounced, and the great majority of them are also from the non-paying class. I now and then see cases in private practice which would be good subjects for hospitals of that sort.

Dr. Baker did not speak of one important point, and that is the legal status of patients in an institution of the kind he described. The epileptics in an insane hospital are all classed as *insane*, can be detained and controlled as if they were insane, and in these hospitals in Germany the status is the same.

Although these hospitals might be very readily filled, the population, I fancy, would be somewhat fluctuating and changing. An adult epileptic is very apt to be self-confident, and make very light of his disease. While he might for a time subject himself to treatment in an institution, there would be the probability that after a shorter or longer time he would insist upon going at large. He would dislike the restraint and confinement of an institution, no matter how pleasant and homelike a character it might possess; and I think, to give such an institution the highest value, the patients ought to be committed as they would be in any private institution for the insane. There is no doubt that such an institution would do great good.

Epilepsy, if curable at all, is curable in the very early stages and in the earliest years and months of the disease, and it would be at that early period that the treatment in such an institution would be of most value. The prospect of cure, however, in any stage of the disease is not brilliant, I must admit; but the benefit to be derived by prolonged care and attention is exceedingly great. Not only is the epileptic very much benefited, but the community and the family are protected from the evils that are consequent upon this condition.

Dr. J. J. PUTNAM: I came here fully impressed with the very great importance and difficulty of this problem, and not at all prepared to offer a solution of it. I feel that the subject is a very large one, and I do not think that even yet we have entirely covered it. There are certain points on which I suppose we shall agree. First, we all should admit, I think, the great desirability of such an institution as Dr. Baker spoke of for pauper epileptics, since they are a great drain

on the happiness and well-being of the families in which they live. Then comes the question of the class of the well-to-do patients. It seems to me the case is quite different, and we are obliged to individualize very much more largely. Dr. Fisher alluded to two points which seem to me of great importance. In the first place, that we should have a right to detain these people so that we might be able to protect the community from such persons as Mr. Sanborn has spoken of.

I have been treating these patients at an out-patient department for twenty years, and I know of many cases of epileptics who live at home happily and support themselves. But supposing persons could not be detained the greater part of their lives in such an institution, they might be kept long enough to ascertain what for them was the best treatment, and their friends and relatives could be urged to carry it out. I agree that the hygienic treatment is by far the most important.

I think such a hospital would be of great service for purposes of study of this disease. When it comes to the life-long separation of such patients from their families, the difficulties become much more manifest. It is doubtful whether we have the right to expose other epileptics to the danger of homicidal patients.

Although children could be made pretty happy in such an institution, it is very doubtful whether adults could be easily made happy in such a place, and I think we are bound to consider their welfare as well as that of their friends. Most epileptics are to a great degree ignorant of the severity of their attacks. In such an institution as this they would have these attacks constantly before their eyes, and it would add greatly to their sufferings.

It seems to me, although such an institution might be very useful, that it should be gotten up, not on the plan corresponding to the colony system, but on the plan of the boarding-out system, which has worked so well with children destitute and difficult to manage. I think it would be possible to find a considerable number of first-rate homes where epileptics could be taken and kept almost singly, and at the same time the advantages of this mode of treatment over that in the hospital, would be, so far as the patients are concerned, very great.

DR. MORTON PRINCE: I am very glad to have an opportunity to endorse the views of the reader of the present paper. It seems to me the need of a hospital of this kind is a self-evident proposition. It seems a most extraordinary fact that while provision has been made for people suffering with almost every other disease, no provision, public or private, has been made for the epileptics. The deaf, dumb, blind, and even persons with nervous prostration, now have a hospital; but the epileptic has nowhere to lay his head. The necessity for such a hospital seems to be shown by the fact that in other countries, on the Continent particularly, they have provided hospitals for epileptics, although not for the particular class to which Dr. Baker refers. I have made attempts to ascertain the number of epileptics in Massachusetts, but they have been unsuccessful. I had the curiosity to see how many cases were treated at the City Hospital in the course of a year. I found that in the course of one year 41 patients applied there with epilepsy. The Massachusetts General Hospital does not publish in tabular form the diseases treated there, but if we assume that the same number apply there, and a similar number at the Dispensary and the Carney Hospital, that would be about 120 a year at

the different hospitals of the city. Of course, that is a mere estimate; so that, as the life of an adult with epilepsy is not particularly shortened by the disease, in the course of ten years 1,200 epileptics would accumulate in the community. Of course, all these cases would not be appropriate for such a hospital as has been described, but a large percentage would. These figures are interesting as throwing some light upon the frequency of the disease as it is met with.

I have found the treatment at the out-patient service of the hospital very unsatisfactory for more reasons than one. It is very difficult to control the patient, to get him to follow systematically any course of treatment. The treatment is not perhaps very encouraging to them. I think there is no question that the treatment would be far more satisfactory, whatever may be its shortcomings, in an institution of the kind outlined by the reader, than by treatment in private practice or in hospitals. I think that an institution should be arranged on very economical principles. The cost for patients should be low, not over that which now obtains in most of our general hospitals, about ten dollars a week. If we estimate that the average patient could pay five dollars per week, that would leave five dollars per week as the cost of each patient to the hospital. I should rather doubt the advisability of farming them out, in the way suggested by Dr. Putnam, in private families. It seems to me the hospital-plan or cottage-plan would be by far the better system. Of course, that is a secondary matter.

DR. F. W. PAGE: I notice that Dr. Baker speaks of epilepsy as generally incurable. I am aware that a great many physicians take a pessimistic view in regard to epilepsy; but I think that a great many cases have been cured, and a great many so far improved as to be useful to themselves and to their families. When I say *cured*, I speak it advisedly. Some patients may not have attacks oftener than once in six months, some once in a year. I can recall cases of epilepsy which have been cured, and have now remained so for many years.

There will always be difficulty attending the getting at the exact proportion of epileptics in the State. It is a matter of serious import to the family. A great many do not like to have it known that they have an epileptic in the family. In the establishment of a hospital it has occurred to me whether it is wise to have it known that it is an *epileptic* hospital, and whether such an hospital might not be joined to some nerve asylum, say, to be considered as a sort of home where patients could have proper care, and not have it definitely known that they had gone to a distinctively epileptic hospital.

The farming-out that has been suggested does not seem to me quite practicable.

I doubt whether it would be advisable to have a single hospital for both children and adults. It seems to me, as the State has provided a small hospital for the care of children, that this could be gradually enlarged, and another one could be built for the care of adults.

DR. WALTER CHANNING: The tendency of modern times has been toward some form of institution-provision for the weak and defective classes, whereby they could receive physical and moral treatment which would improve, or ameliorate their unfortunate condition.

At the foundation of this movement, long before

modern times, there existed the necessity that society should protect itself, and hence all kinds of dangerous persons were shut up like wild animals, that they might do no harm. Anything like reformation or moral treatment was of very little moment.

It is only necessary to refer to the treatment of insane persons to see this exemplified. Up to one hundred and fifty years ago the insane can hardly have been said to have had medical treatment. They were supposed to be possessed by evil spirits, and discipline and punishment were resorted to, to get rid of these spirits. At Bethlem (in London) the treatment was terrible, and nothing could have been worse than that at the Bicêtre.

St. Luke's in London was founded in 1751; and Letchworth says this was the first English hospital where curative principles were put into practice.

By a curious coincidence, the first step toward giving the insane hospital treatment in this country, was taken the same year, that being the date when the insane department of the Pennsylvania Hospital was established by legislative enactment.

Mr. Letchworth says of the latter: "At this time (1751), punishment in one form or another was, in general estimation, regarded as second only to bleeding, purging and dosing. Even when, in 1783, the philanthropic Dr. Rush resolved to relinquish the chains and whips of his day, he still adhered to 'mild and terrifying modes of punishment,' and on paying a visit to an insane man, deemed it one of the first requisites 'to look him out of countenance.'"

During the next fifty years, as every one knows, rapid improvement in the treatment of the insane in *insane institutions under adequate supervision*, took place, though so much cannot be said of the treatment of the insane in almshouses and in their own homes, as the labors of Dorothy Dix amply testify. Still, up to within the last forty years, we will say, the total number of insane in institutions was not large.

In his admirable report made in 1855 to the legislature, Dr. E. Jarvis gave the total number of insane in the State as 2,632, of whom 1,141 were in hospitals. Thirty years after, or in 1885, there were 5,263, according to the general census, which was probably not nearly as accurate as the census of Dr. Jarvis. If it had been, the increase would probably have been larger still, say upward of 6,000, as suggested by the Report of the Board of Health, Lunacy and Charity for 1885.

On October 12, 1885, there were 3,862 insane persons in our State institutions, 3,350 of these being in State hospitals. In thirty years, it will be seen, there was an increase of over three hundred per cent. in the insane-hospital accommodation, the increase in the total number of insane persons being about half that. In the five years since 1885 the number has increased from 3,862 insane persons to 4,701 in our State institutions, a gain of 839 in this short period. The data furnished in a recent bulletin of the Census Bureau show an increase of 73.33 per cent. in the total number of insane persons treated in institutions during the nine years ending in 1893.

These few figures strikingly demonstrate how absolutely essential institution-treatment of the insane has become. They indicate that regular systematic treatment, under medical direction, and supervised by the State, is the chief means whereby a helpless class can receive adequate care.

What is true of the insane is equally true of the other defective classes, but the need, being less urgent, is only just becoming apparent.

Take the idiots, for example. From figures kindly furnished me by Dr. W. E. Fernald, Superintendent of the Massachusetts Asylum for Feeble-Minded, I find there were, in 1880, 76,895 idiots in the United States, only 2,429 of these being in institutions for idiots. During the last ten years, Dr. Fernald thinks the number of institutions for idiots has at least doubled.

We are at last waking up to the fact that idiots can be immensely improved by regular, systematic treatment in institutions, under proper supervision on the part of the State.

Do not the same general arguments hold good in the care of epileptics as in the care of the insane and idiots? They represent a degenerate type of human being prone to sink to a lower level if left uncared for; and, in sinking, they drag down others as well as themselves. They cannot be expected to improve any stock, but to act largely as a demoralizing influence on their environment. They are a weak link in the chain of evolution, and pretty certain to snap unless they can be relieved from the friction and strain of the sound links. Place them under favorable institution and supervisory treatment, and it is inevitable that marked amelioration in their condition will show itself, and the community will be relieved of a menace to the vitality of the race, and a burden on its shoulders which it does not now know how to bear.

These are times when we are making a conscious or unconscious struggle, perhaps, to strengthen the race on its physical side, and one most important means of doing this, is to weed out the weak and degenerate. Place them by themselves where they will do the least harm and receive the most good, and leave the healthy individuals in the community to establish and perpetuate a stronger, sturdier, and better type of man.

DR. BAKER: I only wish to say a word in conclusion. I am quite ready to admit all the criticisms Dr. Putnam has made. In my paper I made no claim, nor did I attempt to cover the whole field of epilepsy. I am too well acquainted with the different manifestations of epilepsy to advocate any such institution; especially of the semi-private kind which I have urged in my paper. I only maintain that a semi-private institution should be established for people of moderate means. I would make it purely voluntary.

The Chair then appointed as a committee to consider the matter brought up by the reader, Drs. T. W. Fisher, Morton Prince, Walter Channing, with Dr. Baker as one of the members of the committee.

#### AMERICAN GYNECOLOGICAL SOCIETY.

SIXTEENTH ANNUAL MEETING HELD AT WASHINGTON, SEPT. 22-24, 1891.

(Concluded from No. 24, page 629.)

Dr. EDWARD A. JENKS, of Detroit, presented a paper entitled,

THE THERAPEUTIC ASPECT OF SOME OVARIAN DISORDERS.

The brilliant achievements of abdominal surgery within the past few years have fairly astonished the medical world. The percentages of recoveries after successful operations on the ovaries and Fallopian tubes

has been large; but there is always a spot on the face of perfection, and unfortunately to operate and to cure have not ever been synonymous terms. There are, undoubtedly, many fatal cases of laparotomy of which, not being published, the medical world has no knowledge. There are also many instances of recovery from operations where the patient is not benefited in the least. I am convinced that some patients whom the gynecologist, at the first examination, believes can only be cured by the removal of one or both ovaries and tubes often recover while the operation is being postponed until a more convenient season arrives. I believe an earnest plea for the salvation of ovaries should emanate from gynecologists or laparotomists themselves.

The author entered a strong protest to the wholesale removal of ovaries by every one considering himself capable of wielding a knife or tying a ligature, not only in large cities but in the villages and towns throughout the country. He believes Battey's operation is requisite in a limited number of cases to secure the establishment of health, but, on the other hand, that many women have been deprived of their ovaries without benefit. Operation for the relief of pain and for mental disorders in anæmic, neurasthenic and hysterical women frequently fails to accomplish the object sought for.

Upon the statements of many laparotomists it can be safely said that ovaries and tubes have been removed for pain or other symptoms when neither macroscopic nor microscopic examination indicated any diseased condition, and the patient restored to health in consequence.

The author suggested that there might be a psychological aspect to the question and related the following case: A lady suffering from hysterical symptoms and worn from long-continued pain attributed to diseased ovaries submitted to a laparotomy for their removal. After opening the abdomen, the surgeon failed to find any pathological condition warranting his completing the operation, and he immediately closed the abdomen. The patient, believing the ovaries had been removed, recovered from the operation, regained her former health and was entirely free from all further pain and discomfort.

It was the opinion of the late Austin Flint, that, to understand any form of disease, one must be familiar with its natural history. The most common of all pathological conditions of the uterus is simple catarrh, and is amenable to treatment. The tubes being offshoots of the uterus, and their mucous lining being continuous with that of the latter organ, it is safe to assert that this same catarrhal condition is found in the tubes. A simple catarrh of any mucous tract in the body, if neglected, often advances to the purulent stage; and I have no doubt that in not a few cases operated upon where pus was said to be found in the tubes, the fluid was simply a mucous secretion slightly purulent, the result of an undiscovered or neglected catarrhal salpingitis, which would have been amenable to treatment by therapeutic measures in its earlier stages. The fearful frequency of gonorrheal salpingitis has caused many to overlook the fact that there is any other.

While the author fully appreciated the feats of abdominal surgery, he believed it was finer science to restore an organ to moderate usefulness and comfort than to remove the offender; but if treatment by

therapeutic means would not bring about the necessary repair, then he would remove the organ without delay. He believed some of these cases had a malarial origin, and had treated some of them accordingly, with success.

Contrasting the rich and the poor in these cases, there is an exception as regards women of the poorest class. They cannot afford a long time of semi-invalidism. They do not complain of sterility, as they generally have more children than they can take care of. The quickest possible amelioration of their troubles is the thing desired; therefore, in these cases operation should be done at once after the operator has satisfied himself that the tubes and ovaries are hopelessly diseased. On the other hand, in the case of the rich who can afford to wait, time and judicious treatment well often bring about the desired result. The uterine sedatives, such as *viburnum piceclia*, *apiol*, some of the coal-tar preparations, bromides, etc., are serviceable in quite a variety of conditions. Electricity is valuable as a general nerve-tonic for the relief of pain and the dissolution of pelvic exudates and adhesions. Local treatment consists in painting the entire vaginal vault with a saturated solution of tincture of iodine, and keeping up continuous pressure by means of wool tampons.

The author referred to the paper of Dr. Wm. M. Polk, "On Certain Operations Designed to Preserve the Uterine Appendages" which, with one or two others of recent date, shows that there is an effort among progressive gynecologists toward a more pronounced conservatism in dealing with pelvic disease than has heretofore existed.

Dr. A. F. CURRIER recalled Dr. Battey's statement, that in the fifteen years he had been performing Battey's operation he had only operated fifty-four times, and, notwithstanding his success, he recommended more careful selection of cases in order to obtain the greatest benefit from the operation.

Dr. COE emphasized the extreme danger of pregnancy and the puerperal state when attended with disease of the ovaries and tubes. He believed some of the obscure cases of puerperal septicemia were due to pre-existing trouble in the tubes and ovaries which was lighted up by fresh inflammation.

Dr. J. M. BALDY believed that cases of insanity, hysteria and mental disturbances were practically non-operative cases, except upon the judgment of an experienced operative gynecologist.

Dr. J. M. BALDY, of Philadelphia, read a paper on  
INSANITY FOLLOWING GYNECOLOGICAL OPERATIONS.

A careful inquiry from the heads of eight hospitals for the insane in the State of Pennsylvania, as to whether any female patients had been admitted into the hospital during the past five years on whom laparotomy was performed and insanity followed, resulted in the following: Out of a total of fifteen cases, in eleven cases there was pre-existing insanity, and the operation was undertaken in the main for the cure of the mental condition. In four cases insanity followed the performance of laparotomy; one died, and one recovered from the insanity. Many of the mild cases recover quickly; a certain proportion of the severe cases terminate fatally.

The author's conclusions were: (1) That cases of serious mental derangement might occur after operation in a person without a family history of insanity.

(2) That mental disorders were no more likely to follow operation on the sexual organs than on other parts of the body. (3) That the accident was as frequent in men as in women. (4) That operations acted as a determining cause to mental derangement where there was a previous tendency. (5) Emotional disturbance is greater at the time of surgical operations. Where there is an inherited tendency to mental disease, laparotomy should only be undertaken with an understanding of the possible outcome, and should not then be done, unless the case was urgent. (6) Mental disturbance following gynecological operations is more frequent than is generally supposed.

DR. THADDEUS A. REAMY, of Cincinnati, read a paper on

SOME CLINICAL TESTIMONY AS TO THE ULTIMATE RESULTS OF REMOVAL OF THE UTERINE APPENDAGES.

The material on which the paper was based was restricted to cases of which the author had obtained a reliable history of the patient's condition for from two to five years after operation; excluding all cases of ectopic gestation, and tumors and malignant disease of the ovaries. The operations were performed from 1885 to 1889; there were 163 cases in all, 109 married, 10 widowed, 44 single. In 144 cases both ovaries and tubes were removed; in 15 cases but one ovary; in seven cases such extensive adhesions and destruction of tissue by disease that operation was discontinued after liberating, as far as possible, adhesions (cases doing well); in 12 cases appendages removed for arrest of hæmorrhage and growth of fibroid tumor (in none of these did the growth ascend above the umbilicus); in six cases for hysterio-epilepsy, three of which were cured; in three cases for neurotic symptoms (one cured, one improved, one made worse). Pyosalpinx was found in but 17 cases out of the 163; parenchymatous salpingitis in 29 cases. Hydrosalpinx; with disseminated cystic degeneration of both ovaries, was found in 30 cases; of one ovary, in only 26 cases.

Results: Cured, 40 cases; improved in general condition, 60 cases; temporarily improved, but relapsed after a year or two, 30 cases; apparently worse after operation, 10 cases.

In every case where both ovaries were thoroughly removed menstruation ceased within six months, generally at once. In several cases uterine hæmorrhage occurred subsequently, but was not menstruation. Reliable testimony from 14 married cases showed, in 14, sexual appetite extinguished with menstruation; in seven, lessened; in 16, not influenced; in seven, markedly increased.

Conclusions: (1) Pyosalpinx does not exist in nearly so large a proportion of cases of pelvic disease in the middle and upper classes as is generally thought. (2) In cases from this class gonorrhœa does not play nearly so important a rôle in the cause of disease of tubes and ovaries as generally believed. (3) In properly selected cases, where otherwise incurable disease of the appendages exist, the results from surgical interference are not only satisfactory but brilliant. (4) In properly selected cases the removal of the uterine appendages offers more promise for the relief of hysterio-epilepsy than is generally conceded. (5) The practice should not be continued in the treatment of purely neurotic cases. (6) Many cases of manifest pelvic disease, including disease of the ovaries and

tubes, which are cured by removal, could be as thoroughly and promptly and more satisfactorily cured by more conservative methods without the sacrifice of these important organs. (7) Many cases reported by operators as cured are found after a few years to be no better off than before operation. (8) The arrest of menstruation after the removal of the ovaries in so large a number of cases tends to confirm the belief that the ovaries bear an important relation to this function. (9) The influence of the removal of the appendages upon the sexual appetite has heretofore not generally been properly stated. (10) The relation of this influence to this function and the psychoses which so often followed to mar the otherwise satisfactory results of this operative procedure must now be fully conceded.

DR. JOSEPH TABER JOHNSON thought the removal of the appendages for a small bleeding fibroid was most justifiable and saved the patient from the horrors of a subsequent hysterectomy. He agreed with Dr. Reamy that the neurotic cases were the most difficult to treat. It might be well to give such patients the chance of the benefit that might follow operation, but always with the full explanation that there was no certainty that it would succeed. He doubted the advisability of operating for dysmenorrhœa, as there were many other methods of treating it successfully, and thought the operation should be restricted to cases where there was positive disease of the tubes and ovaries which could be determined by palpation.

DR. GILL WYLIE was surprised that Dr. Reamy had done such a number of incomplete operations. In his experience of over four hundred operations for diseased tubes and ovaries, he had never done an incomplete operation, and without losing many patients. He had had a return of menstruation in about five per cent. of his cases, due, he believed in every case, to other conditions of the uterus not cured by the operation.

DR. S. C. GORDON agreed with the writer in regard to neurotic cases. He had observed that the symptoms increased about the period of menstruation; when everything else had been done that could be done, without effect, he would operate. He was much opposed to the experimental method of treating these cases, curetting, tamponing, iodining, etc., for four or five years, in order to find out what the trouble was.

DR. COE thought true menstruation after the removal of tubes and ovaries a very rare occurrence, but he was convinced that profuse uterine hæmorrhage did sometimes continue for one, two or three years. He had operated three times on one woman to ascertain the cause of profuse hæmorrhage, but could demonstrate nothing beyond the presence of firm adhesions. Several small nodules were removed from the stumps of the tubes, but no ovarian tissue was found. Persistent hæmorrhage may be due to adhesions, or sometimes to cysts of the broad ligament, and in a very large class of cases to hypertrophic endometritis, the uterus not undergoing ordinary atrophy.

The following officers were elected for the ensuing year: President, Dr. John Byrne, of Brooklyn; Vice-Presidents, Dr. R. B. Maury, of Memphis, and Dr. Cornelius Kollock; Secretary, Dr. Henry C. Coe, of New York; Treasurer, Dr. Matthew D. Mann, of Buffalo; Council, Drs. J. W. Chadwick, Boston, M. T. Hanks, New York, S. C. Gordon, Portland, Maine, J. E. Janvrin, New York.

THE BOSTON

## Medical and Surgical Journal.

THURSDAY, DECEMBER 17, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.*

**SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.

THE ORIGIN AND NATURE OF INFECTIOUS DISEASES.<sup>1</sup>

THE Croonian Lectures lately delivered at the Royal College of Physicians, London, by Dr. J. Bardon Sanderson, have been of uncommon interest. Dr. Sanderson chose as his subject "The Progress of Discovery relating to the Origin and Nature of Infectious Diseases"; and in the course of his inquiries entered upon the much debated question of "The Origin and Development of the Doctrine of the Infectious Nature of Inflammation," which was the topic of the first two lectures. These lectures are timely as effectually disposing of the notion (which, at least, must be abandoned till clearer light has been obtained) that the congeries of phenomena constituting inflammation is always and necessarily the result of microbe-invasion and microbe-action.

Regarding inflammation as a process characterized by the formation of pus, and having its seat in the capillaries, Dr. Sanderson shows that this is essentially the result of an injury done to the tissues by chemical agents of a certain intensity, and that the dictum of Weigert, "no suppuration without bacteria" is untenable. In fact, he asserts that the proximate cause of inflammation is always chemical, and to justify this proposition, he endeavors to show, first, that inflammation (that is, suppuration) can be produced by chemical agents in the absence of microphytes; and, secondly, that when it is produced by microphytes, the action is chemical.

The second point he thinks is sufficiently established by a series of observations, extending over about eight years, made by a number of highly competent bacteriologists. The essential feature of these methods of experiment is to introduce sterilized irritant liquids, either subcutaneously or into serous cavities, using precautions to preclude the entrance with these of microphytes.<sup>2</sup> One of the first of the more exact investigations of the subject was that of Corneliman, and consisted, first in charging capillary tubes with the

liquid to be experimented with, closing the ends hermetically, and then, after sterilizing the tube and its contents, introducing it under the skin and closing the wound antiseptically. After it had remained for several days, it was broken between the fingers so as to discharge its contents subcutaneously. Similar experiments were performed by Scheuerlen, who substituted fusiform for cylindrical tubes, and contrived to introduce the contained fluid very slowly into the subcutaneous tissue and into the peritoneal cavity. The chemical substances used were very various: mercury, nitrate of silver, turpentine, croton oil, etc. Mercury was found to produce suppuration in the dog, not in the rabbit. When injected hypodermically in the dog, each drop becomes the centre of a minute abscess. Silver nitrate, in five per cent. solution, produces suppuration in the dog but not in the rodent. Ammonia fails to produce pus in any animal. Turpentine produces suppuration with great certainty in the carnivora. The organic action of croton oil is similar but inferior. In all these experiments, the materials used are sterilized and introduced with the most rigid antiseptic precautions, and the pus obtained is tested by cultivation, and cover-glass preparations are subjected to microscopic scrutiny. In every instance, provided that the experiment has been properly performed, the inflammatory-exudation liquid is sterile. These experiments seem to show, not only that suppuration can be brought about without the concurrence of microbes, but that the readiness with which pus is formed depends on conditions which belong to the animal, rather than the noxa. In the dog, a sterile abscess can be produced at ease with such different agents as mercury and turpentine, but it is much more difficult to obtain the result in a rodent.

The other point in Dr. Sanderson's contention, that when micro-organisms are directly concerned in the production of inflammation, the mode of action and the proximate cause are still chemical, is based on the fact that not only in the case of staphylococci, but in that of many other micrococci, the symptoms which result from the presence of the microphytes themselves in the living organism, can also be produced by the soluble chemical products of the vegetation. So long ago as 1878, Pasteur showed that cultures of the *microbe g n rateur du pus*, which had been sterilized, were as capable of producing abscesses as living cultures are, and that the resulting pus was sterile; but it was not until a few years ago (1887) that Grawitz made similar experiments with pure cultures of pyogenic microbes, particularly with the ordinary staphylococci. Since then various other experimenters have investigated the subject in relation to this and other pus-producing microphytes, with the general result that in carnivora sterile abscesses can be produced with the same certainty by the injection or introduction of devitalized cultures of staphylococci as by turpentine or mercury. In rabbits, where a Cohnheim's tube, charged with such sterilized cultivation, is used, the same phenomenon presents itself as if the tube con-

<sup>1</sup> The Croonian Lectures, for 1891.

tained creton oil — leucocytes creep in at the end and die and form pus.

From a consideration of the more recent and accepted investigations as to the morbid agents in tuberculosis, typhoid fever, pneumonia, tetanus and diphtheria, as well as in relapsing fever, splenic fever of animals and inflammation or, its characteristic result, suppuration, Sanderson is disposed to deduce two types of morbid action: biotic and toxic. Biotic agents act mainly by virtue of their endowments as living organisms; toxic agents chiefly by virtue of the toxins which they produce. That is, the *nexus* between the morbid agent and the morbid process is, in the one case, dissemination, in the other diffusion.

As to the causal relation between microphytes and the diseases they produce, it is necessary to bear in mind, also, the possible substitution, under certain conditions, of one species for another.

Recent researches have, furthermore, taught that the toxicity of a disease-producing microphyte is even more essential to its effects than its adaptability to a living nutritive medium. The question of infection, therefore, has become more and more chemical and less morphological. The employment of the bacteriological method is, however, none the less necessary, and the pathologist must continue to perfect himself in the technique which Koch has created. If the questions at issue appear, for the moment, to be chiefly chemical, it is only that we have passed from the form to the substance, from the agent to the action. Our interest in microphytes is not as botanical species, but as makers of toxins; and in toxins is not as chemical compounds, but as disease-producers. The contest in the organism between invading microphytes and the living elements of the invaded territory is not a hand-to-hand fight between tissue elements and microphytes (Metschnikoff), but one in which both act (so to speak) at long range, in which the weapons are poisons and counter-poisons, toxins and anti-toxins — words implying that the pathological endowments of these bodies are antagonistic. We have on the one hand, products allied to modern proteids, to ptomaines or leucamines, on the other hand, the old *vis medicatrix naturæ* or *vis proteatrix*, most recently designated as a component of the *liquor sanguinis* (Behring and Kitasato).

#### EPIDEMIC INFLUENZA.

It seems to be the general impression that epidemic influenza has once more made its appearance in the United States, though as yet it has not assumed a serious aspect.

It is just two years since the violent outbreak of 1889 '90 commenced. At that time the epidemic followed mild and damp weather, and as this season has been remarkably dry, the weather would seem, as in times past, to have very little to do with its production. In his report on the health of the city of New York, for the week ending December 12th, Deputy Registrar

Nagle says: "Influenza, which was reported as causing a large number of deaths in some European cities and a few cities of this country, was reported to have caused three deaths in this city during the week. The deaths from this cause were associated with other affections, and were in very old persons. Pneumonia, which is a most frequent complication in this affection, caused 112 deaths, which is an increase of 18 deaths over the preceding week, and is ten above the average of the corresponding week of the past five years."

During the week, 734 deaths were reported in New York, which is an increase of 59 over the week ending December 5th, and represents an annual death-rate of 22.48 to every 1,000 of the estimated population. The number of deaths is, however, 25 less than the average for the corresponding week during the past five years.

The Boston Board of Health does not officially recognize the presence of epidemic influenza in the city, but admits the apparent increase of catarrhal troubles and pneumonia during the last month. This, in itself, is not unusual at this season of the year, but practitioners are meeting with increasing numbers of cases exhibiting sore throats associated with pains in various parts of the body and digestive disturbances, which recall in a mild way our previous experience. There is no occasion for sensational alarm. But, bearing in mind the reports from all over Europe; from Great Britain, where the east coast of Scotland and the west coast of England have been especially visited; from Australia and New Zealand — reports which indicate the probability of a pandemic — it behooves the old, the feeble, and those who habitually overwork, to live prudently.

#### MEDICAL NOTES.

NO TRICHINÆ IN AMERICAN PORK. — In the German Reichstag recently, the Minister of the Interior said that no trichinæ had been found in pork imported from the United States, since the bill providing for the inspection of pork had become a law.

MEMOIR OF DR. FORDYCE BARKER. — The many friends of the late Dr. Barker will greatly appreciate the memoir by Dr. William T. Lusk, which appeared in the *Medical Record* of November 21st. Dr. Barker's relations to the profession were such, that this short sketch of his personal life will be read with interest by physicians in all parts of the world.

MARINE-HOSPITAL SERVICE. — The report of the Supervising Surgeon-General shows that during the last year there were 52,992 sailors treated in the various marine hospitals and dispensaries. There were 1,182 pilots examined for color-blindness, of which number 29 were rejected. There were 1,664 vessels inspected at the national quarantines, of which 113 were detained for disinfection. At the Gulf Quarantine Station, on Chandeleur Islands, 46 vessels, badly infected with yellow fever, were held and disinfected, and twelve yellow-fever patients were taken from these

vessels into the lazaretto. As a result not a single case of yellow fever developed on the coast guarded by this quarantine. Attention is called to the increased number of cases of leprosy discovered in the United States, and suggests the necessity of a national asylum. Owing to the prevalence of cholera in the East, and to want of uniformity in the local health regulations at several of the ports of entry in the United States, a circular has been recently issued prohibiting the entry of rags imported from Marseilles unless previously disinfected.

**PROTECTION FOR RAILROAD EMPLOYEES.**—In his annual message to Congress the President says: "I have twice before urgently called the attention of Congress to the necessity of legislation for the protection of the lives of railroad employees, but nothing has yet been done. During the year ending June 30, 1890, 369 brakemen were killed and 7,841 maimed while engaged in coupling cars. The total number of railroad employees killed during the year was 2,451, and the number injured, 22,320. This is a cruel and largely a needless sacrifice. The Government is spending nearly \$1,000,000 annually to save the lives of shipwrecked seamen; every steam vessel is rigidly inspected and required to adopt the most approved safety appliances." He recommends the compulsory introduction of automatic couplings for freight cars.

**MORALS IN THE DISTRICT OF COLUMBIA.**—Concerning this subject the President says: "The Attorney-General and also the Commissioners of the District of Columbia call attention to the defectiveness and inadequacy of the laws relating to crimes against chastity in the District of Columbia. A stringent code upon this subject has been provided by Congress, for Utah, and it is a matter of surprise that the needs of this district should have been so long overlooked."

#### NEW ENGLAND.

**BOSTON CITY HOSPITAL.**—The Common Council has adopted an order to borrow \$136,500 for the use of the City Hospital, to be expended as follows: brick walls, \$10,500; electric-light plant and boiler-house, \$35,000; estates, East Chester Park and Harrison Avenue, \$65,000; alterations in the above, \$10,000; stable and disinfecting building, \$16,000.

**HARVARD MEDICAL SCHOOL ASSOCIATION.**—The first bulletin of the Association, containing the constitution, list of officers, records of the first meeting and the annual dinner, has just appeared. The Association was formed last spring for the purpose of furthering the interests of the school and of the graduates. It is proposed to publish in the spring a complete catalogue of the members. The canvass among the graduates has necessarily been very incomplete, and many have never heard of the Association. The membership now numbers 835. All graduates of the school who have not received the above-mentioned bulletin are requested to send their names to the secretary, Robert W. Lovett, 379 Boylston Street, Boston.

**IMMIGRANTS AT PORTLAND.**—For six months, beginning November 15th, the Allan and Dominion steamship lines, land their passengers at Portland, Me., instead of at Halifax. It is estimated that they will bring thirty-five hundred immigrants, who by the law passed by the last Congress, should receive medical inspection. For this purpose a surgeon of the Marine-Hospital Service has been detailed.

#### NEW YORK.

**THE EXECUTION OF LOPPY.**—All the medical witnesses present at the execution of the murderer Lopy at Sing Sing prison, on December 7th, who have expressed an opinion on the subject, agree in the statement that death was painless and instantaneous, although, by way of precaution against any possible doubt, the application of the electrical current for a few seconds, was repeated several times.

**POST-GRADUATE SCHOOL LYING-IN DEPARTMENT.**—Through the generosity of Mrs. C. P. Huntington and other ladies, the New York Post-Graduate Medical School and Hospital has been enabled to open a well-equipped lying-in department, which is under the general direction of Dr. C. A. Ramdohr, and the nurses for which are supplied from the College Training School for Nurses.

**THE MEDICO-LEGAL SOCIETY.**—At a meeting of the Medico-Legal Society held December 9th, H. M. Somerville was elected President, Mr. Clark Bell, who has so long held this position having declined a renomination. The other officers elected were as follows: First Vice-President, Dr. Peter Bryce, of Alabama; second Vice-President, Albert Bach; Corresponding Secretary, Moritz Ellinger; Secretary, Clark Bell; Treasurer, Dr. Matthew D. Field; Chemist, Prof. H. A. Mott, Jr.; Permanent Commission, Judge John F. Dillon, of New York, and Dr. W. W. Godding, of Washington, D. C.; Librarian, Dr. Thomas Chelland; Assistant Librarian, Dr. G. Bettini de Moise; Curator and Pathologist, Dr. J. Clark Thomas.

**DR. JOSEPH D. BRYANT,** who has been Surgeon-General of the State under Governors Cleveland and Hill, has been reappointed by Governor-elect Flower to the position which he has filled with so much credit to himself and the militia service.

#### Miscellaneous.

##### ADAMKIEWICZ TREATMENT OF CANCER.

A few months ago we noted that the Austrian Minister of Education had invited Professor Adamkiewicz to come to Vienna, and had placed some of the material in the surgical clinic at his disposal. This was in consequence of an announcement by Adamkiewicz that he had discovered a cure for cancer. He did not divulge his method, and it is even now still a secret, except that it is through the medium of subcutaneous injections.

In summing up a recent report from Vienna, the

*Medical Press*, November 25th, says in a leading article that in a ward under the charge of Professor Billroth, Adamkiewicz was permitted to experiment upon a patient who was believed to be affected with epithelioma of the upper and lower lids of the right eye. The history showed that the disease was rapidly spreading, and, under the circumstances, therefore, the case seemed a most suitable one for testing the value of the new treatment. On October 25th the professor took the patient in hand, the result being that on November 12th the sufferer was discharged from the hospital—cured. In other words, after eighteen days treatment an epithelioma of the upper and lower lids was pronounced by Adamkiewicz to have perfectly cicatrized over. Naturally enough, upon this matter Professor Billroth had something to say, and what he has said can scarcely be deemed to be enthusiastically favorable to this latest form of cancer curing. Billroth remarked that he had no doubt about the case being one of epithelioma. It was true also that the growth had cicatrized at the centre and in the periphery. But whether it was a growth possessing distinctly malignant characters was open to some doubt. No signs of secondary infection had been noticed, nor was there any enlargement of the nearest lymphatics. Again, it had repeatedly cicatrized after treatment by caustics and “scrapings.” Upon the whole Billroth contended that Adamkiewicz’s treatment had accomplished nothing, and that our knowledge of the subject of the treatment of cancer had not been in any way advanced by these experiments. Professor Kaposi said that he had treated the same patient fifteen years ago for the same kind of growth, and obtained a successful result by the application of caustic. He quite agreed with Billroth in the belief that the epithelioma was not a malignant formation in the usual acceptance of the term. He expressed a wish to know how Adamkiewicz performed his experiments—whether the injections were made locally or otherwise. Still more condemnatory of the new treatment were the remarks of Dr. Franks, who spoke on behalf of Professor Albert. According to the latter observer, the experiments conducted in his clinique by Professor Adamkiewicz appeared to have very little influence over the new growths, and he believed that massage or any other unmechanical irritation would have the same effect in reducing the size of the tumors. There was nothing, in his opinion, in the new treatment which could be considered of any real value.

#### INFLUENZA.

ACCORDING to the *Lancet* a noteworthy difference between the present outbreak of influenza and those experienced last spring and the original epidemic of the winter of 1889-90 is the comparative slowness of its diffusion over the country. It was, in November, mainly confined to two widely-separated parts of the kingdom, Cornwall and the eastern counties of Scotland. It is remarkable that children are being attacked almost as much as adults. It is reported to be very prevalent in St. Petersburg and Berlin, whilst at Hamburg it reached “alarming proportions,” and the weekly mortality of the city and its suburbs exceeded the average by 280. In France it is especially prevalent at Bordeaux, where many deaths among the aged have occurred. It has, also, appeared in Paris.

In showing some patients to his students a few weeks ago Professor Gerhardt, of Berlin, said,<sup>1</sup> “The morbid symptoms which we comprehend under the collective name of influenza have repeatedly been observed before, and several epidemics of the so-called ‘grippe’ (those of 1847 and 1876, for instance,) are on record. Such a pandemic, however, as prevailed two years ago had not occurred for a generation, and we had to deal with something quite new and unknown. It came to us from the East. In May, 1889, it broke out in Bokhara, rapidly overran Russia in Asia, and came to St. Petersburg in September. The disease spread rapidly all over Europe, radiating over the provinces from Berlin, Vienna, Paris, and London, and remaining mostly three or four weeks, never more than two or three months, in one place. Its course ran unmistakably from east to west; from us it went to America and then on to Eastern Asia. Now it seems to have arrived among us again after its journey round the world. The symptoms are remarkably various. The malady often takes an easy course, and is in general not very dangerous to robust people. It begins in most cases with high fever, which rapidly abates. In the graphic representation of the progress of the fever the steep and narrow one-day’s curve seems to be characteristic. A vast number of sequelae have been observed. Already existing diseases, such as pulmonary tuberculosis and diseases of the heart, often take an unusually rapid and fatal course under the influence of influenza. Influenza must be reckoned among the acute infectious diseases, and its contagious character may be regarded as proved. The spread of the disease is uncommonly rapid, and the time of incubation is often less than twenty-four hours, never more than two or three days. The question whether one attack protects the patient against future ones cannot be definitely answered; some immunity there must be, for the epidemic never lasts very long. Children are seldom attacked, sucklings never. Some people are temporarily insusceptible. Doctors, for instance, have often fallen ill at the end of the epidemic. The age from fifteen to twenty-five seems to be the most susceptible. No specific against the disease is known; the doctor must therefore confine himself to symptomatic treatment.”

#### CONSANGUINEOUS MARRIAGES.

DRS. LOUIS and GUSTAV LANCY have published an article on this subject in *L'Union Médicale*, No. 24, 1891.<sup>2</sup> It is based upon the study of a little community in the north of France in which all the inhabitants are related to each other. Probably the majority of the early marriages were among blood relations, and now twenty-four per cent. of the marriages are among consins of not more than two removes. Of these marriages, sixty-three in four years, there were defects in but two children. In both of these instances, there seems to be some reason other than the relationship for the defect. Sixteen per cent. of the marriages were without fruit, and in about eight per cent. there had been but one child. The authors conclude that marriage of blood relations tends to the diminution of the birth-rate, but that it has no prejudicial influence upon the children that may be born in such union.

## THERAPEUTIC NOTES.

**URTICARIA.**—Quinquand treats urticaria as follows: <sup>1</sup> Internally alkalies, or if they are not sufficient, arsenic or naphthol. Externally a wash composed of

R Acidi borici . . . . . 3 i.  
Chloral . . . . . 3 i.  
Aque . . . . . 3 vi. M.

or a powder

R Acidi salicylici . . . . . 3 i.  
Zinci oxidi . . . . . 3 i.  
Amyli . . . . . 3 vi. M.

**TREATMENT OF VOMITING OF PREGNANCY BY ELEVATING THE PELVIS.**—Grant<sup>2</sup> reports cases of obstinate vomiting of pregnancy in which great benefit was obtained by lowering the head and shoulders, and placing several pillows under the sacrum, and continuing the position at intervals for a few hours.

**BENZINE AS A PREVENTIVE OF TRICHINOSIS.**—Puttee<sup>3</sup> reports that being called to see twenty-seven persons who had a few hours before eaten a pig, which was discovered to be full of trichinae, he administered forty minims of benzine in capsules, followed by a cathartic. Eight months later no case of trichinosis had occurred among them.

**STRYCHNINE FOR DRUNKENNESS.**<sup>4</sup>—In consequence of the remarkable success claimed in the treatment of drunkenness with hypodermic injections of strychnine, this method of treatment was tried in the city hospital in Görlitz, Silesia, but the results were almost entirely negative.

## Correspondence.

## SOME POINTS IN OCULAR THERAPEUTICS.

SALEM, December 5, 1891.

MR. EDITOR:—It would have been well for the man who was led into my office last week, because of occluded pupils after iritis, if his doctor had read the timely article by Dr. Cheney that appeared in the JOURNAL of June 4th. At present it should surely be known by every practitioner, that his chief effort in treating a case of iritis is to keep the pupil dilated.

Occasionally some other mydriatic may have to be substituted for the salts of atropia. For example, in May, 1889, a young gentleman sought relief because of specific iritis in his right eye, of a week's duration. As the iris was attached to the capsule of the lens in place, a solution of atropine sulphate was ordered (0.15-15.0), which soon gave a round pupil. But at the end of a week there was an intense erythema of the lids and cheek. Possibly this may have been increased by the frequent applications of hot water. However, on suspending the instillations of the atropine and substituting in its place dibutisoine sulphate (0.03-4.0), the swelling soon subsided and the case went on to recovery (with normal vision). Last year a married sister of the above used atropia to relieve the pain in scleritis, and she was affected by it as her brother had been.

In the JOURNAL of October 31, 1878, the writer called attention to the peril that attends the indiscriminate use of atropia, especially when there is a possibility of the presence of glaucoma. Since then other patients have been seen where atropia was prescribed most unhappily. One was an old woman, whose physician had ordered this agent

to be used so frequently that a woman was employed to drop it between the lids during the night. When she came to me she was unable to count fingers, though she could locate a lighted lamp, and the eyes presented the usual symptoms of glaucoma. The trouble had lasted twelve days. Eserine sulphate (0.10-15.0) having no effect, she was taken to Salem, where an iridectomy was done on both eyes, under cocaine (which did not render the operation painless, and this has been my experience in operating in glaucoma). When last seen her vision was two-thirds of normal.

If the use of a strong solution of atropia (either with or without cocaine) in iritis causes dryness of the throat, it is well to have the patient press a finger over the caruncle when the drop is instilled, and to keep up the pressure for a moment till the surplus has been wiped away. For an eye-dropper, experience for some years has convinced me that nothing is better on many accounts, than a teaspoon. Patients are told to pour some of the liquid into the spoon and then to pour it back into the phial, that a drop will remain on the tip of the spoon which can then be dropped on the inside of the lower lid, which is to be held down while winking takes place, and the eye-water is thus largely absorbed.

The danger of infection should always prevent the use of an old medicine dropper. An alarming phenomenon has been noted by several patients who have come to me because of widely dilated pupils. On inquiring, it was found that a dropper had been used in treating a slight conjunctivitis that years before had been atropia in an iritis. It is almost impossible to remove atropia from an old dropper, that is from the rubber nipple.

Very respectfully,

D. COGIN.

## Address.

THE PRINCIPAL TYPES OF PHYSICAL TRAINING COMPARED.<sup>1</sup>

BY EDWARD MUSSEY HARTWELL, PH.D., M.D.,  
*Director of Physical Training in the Public Schools of Boston.*

(Concluded from No. 25, page 644.)

In Guhl and Koner's "The Life of the Greeks and Romans," we find the gymnasia mentioned first among the public buildings of Greece, because they were "centre-points of Greek life." The authors go on to say: "Games and competitions formed a chief feature of their religious festivals. This circumstance reacted both on sculpture and architecture, in supplying the former with models of ideal beauty, and in setting the task to the latter of providing suitable places for these games to be celebrated. For purposes of this kind the palaestra and gymnasium served. In earlier times these two must be distinguished. In the palaestra, young men practised wrestling and boxing. As these arts were gradually developed, larger establishments, with separate compartments, became necessary. Originally, such places were kept by private persons; sometimes they consisted only of open spaces, near a brook if possible, and surrounded by trees. Soon, however, regular buildings, gymnasia, became necessary. At first they consisted of an uncovered court surrounded by colonnades, adjoining which lay covered spaces, the former being used for running and jumping, the latter for wrestling. In the same degree as these exercises became more developed, these institutions grew in size and splendor.

"Minute descriptions of these establishments, by Greek authors, we do not possess, but the important facts are known to us from occasional remarks, particularly in the Platonic dialogues. There we find mentioned the *ephebeion*, where the youth used to practice; further, the bath, to which belonged a dry sweating bath, for the use of both wrestlers and visitors. The *apoduterion* was the room for undressing. In another room, the *elaiotheson*, the oil was kept for rubbing the wrestlers, and there possibly this rubbing itself took place. In the *konisterion* the wrestlers were sprinkled with sand, so as to give them a firmer hold on each other. The *sphairsterion* was destined for games of ball, while other passages, open or covered, were used for practice in running, or simply for walking. A particular kind of covered passage were the *zusto*, which had raised platforms on both sides for the walkers, the lower space being used by the wrestlers.

"At Athens the gymnasia were public institutions supported by public or private means, at which *epheboi*, youths old enough for military service, and men spent a part of the day in athletic exercise and in instructive and social intercourse. These were the *Lukasion* (Lyceum), the *Kynosarges*, the *Akadenia* (Academy), the *Ptolemaion*, the splendid gymnasium of Hadrianus, and the small gymnasium of Hermes. The number of palaestra at Athens was still greater. They were all private institutions kept by single *paidotribai*, and destined for the athletic education of boys only. In smaller cities the joint practice of youths and men was frequently inevitable."

The teachers of gymnastics among the Athenians were known as *gymnastai* and *paidotribai*; the former having to superintend the general development and training of the body, while the latter directed the single exercises. The *sophronistai* were responsible for the good behavior of the boys. The whole *gymnasion*, and all its teachers, was under the charge of a superintendent, termed the *gymnasiarchos*. The principal exercises taught in the palaestra and the gymnasium were running, leaping, wrestling, throwing the discus, throwing the spear, boxing, and the pancration, a combination of boxing and wrestling.

Various games of ball were in vogue, and much attention was paid to swimming and bathing. It is held by some that the Greeks at times engaged in boat-racing. If so, the sport formed no part of the athletic canon. The Greek training was severe; that of candidates for the Olympic games lasting for ten months. It was mostly conducted in the open air, often under a blazing sun. In their practice exercise and in their matches, the athletes were naked. They were oiled and sanded before their exercise, and scraped with a strigil, shampooed and bathed after it. Their dietary was also carefully regulated. So, too, were their hours of sleep and practice. In none of our five national systems of exercise has "training" been carried to so high a pitch, or been so well ordered, as it was among the Greeks. So far as I know, no attention was paid to dietetic rules by the contestants in either knightly or popular games in the Middle Ages, and "training," in the sense in which it is employed by those who are addicted to British sports, has practically no followers in Germany or Scandinavia, outside the ranks of professional acrobats and a few Anglo-maniacs.

The Greeks used but little apparatus, either in their preparatory exercises, which were made in the palaestra and gymnasium, or in their match-games, which usually, as at Olympia, took place in the *stadion*, or some other uncovered place; and such apparatus as was used was of the simplest kind. The spear, the discus, possibly the vaulting pole, the *halteres* and *himantes*, which are the prototypes respectively of our dumb-bells and boxing-gloves, pretty nearly exhaust the list of Greek gymnastic machines. The Grecian *halteres*, somewhat resembling our dumb-bells, were used by jumpers, who carried one in each hand when in the act of leaping. The Romans used *halteres* much as we use dumb-bells, for building up the muscles of the arms.

Machine or apparatus gymnastics are mostly of modern origin. Jahn invented the parallel bars, and the horizontal bar. The stall bar, the swinging ladder and the "Bom" are Swedish devices. Most of the ropes, ladders and poles used in gymnastic climbing have been adapted to modern uses, and cannot be classed, generically, as distinctively Swedish or German. Boucicaut, a famous French medieval champion, could, we are told, ascend and descend ladders, using his hands alone, while in full armor. The physical training of page and squire, was chiefly directed to making him a good horseman, and to rendering him skilful in the use of sword, lance and maul, while in the saddle; and the newly dubbed knight must be able to leap into the saddle while in full armor. The aspirant to knighthood practised, with his sword, at posts and the Saracen's head; and learned lance-ship by tilting at the ring and the quintain; horse-

<sup>1</sup> The substance of this article was delivered on May 9, 1891, as the last of six Hemenway Lectures on Physical Training, by the writer, at the Old South Meeting House, Boston.

yond these he had little need for fixed apparatus. The gymnastic horse of wood, so popular everywhere among heavy gymnasts, to-day, is clearly of chivalric origin. I am not able to say when it was first used to supplement or to supersede exercises upon the living animal, but mention is made of it in the sixteenth century. As might be expected, we shall find more "mediaeval survivals" in the exercises and tactics of the modern cavalryman than in those of the infantryman.

But the Greek gymnasium was much more than an aggregation of wrestling-pits, running-tracks, exercise-halls, and bathing-establishments, surrounded by colonnades and shady walks. The Athenian gymnasia were clubs and schools as well, provided with lecture-halls and quiet nooks to which the elders of the city resorted for instruction and social intercourse. It is noteworthy that, even among the Greeks, the word *palastra* came to mean a school, and that the most highly educated of modern peoples, the Germans, designate the highest of their secondary schools by the term *gymnasium*. The French word *Lyceé*, derived from Lyceum, the name of the gymnasium in which Socrates and Aristotle taught philosophy, is used in the same sense as the German *gymnasium*. Antisthenes, the founder of the Cynic school of philosophy, taught in the Kynosarges gymnasium. The masters in art and science, the world over, are content to be styled Academicians, in memory of the Academy of Plato, which was one of the public gymnasia of Athens.

The most notable athletic and gymnastic gatherings of our own day are, in a sense, more truly popular than were any of their forerunners; since the masses take part in them, not only as spectators, but as contestants. The great festivals of the German Turners, also, which recur every few years, are peculiarly folk-festivals. They, and the great events of the athletic year in England, — such as the University Boat-Race, the Royal Henley Regatta, the Eton and Harrow, and the County Cricket-Matches, the Lilliebridge Athletic-Sports, and the Foot-Ball Match between the All-Scotland and All-England Elevens, — each and all, excite great interest, and draw immense crowds of spectators. The chivalric tournaments were often signalized by gorgeous pageants, elaborate merry-makings, and stately ceremonials, and were graced by throngs of on-lookers, both gentle and simple. But the sacred games of the Greeks surpass them all as regards significance and splendor.

Olympia, in Elis, where the most famous of the Grecian contests were held for five days every fifth year at the time of the first full moon after the summer solstice, was a festival city. As I pointed out in a former lecture, it not only included a stadion (or race-course), two gymnasia and a hippodrome, but was adorned with temples and other public buildings, with monuments to kings and heroes, with treasure-houses, and with hundred of statues erected to the memory of victors in the games. Here assembled, not only the flower of Greek manhood, but also delegates of empires and cities, and throngs of spectators from distant shores, to witness the athletic contests, the chariot-race, and the competition between poets, dramatists and artists; and to participate in the sacrifices and procession in honor of Zeus to whom the place and festival were sacred. Athletics and gymnastics have never played so large and dignified and prominent a part in the life and affairs of any nation as they did among

the Greeks. We may not hope that any modern people will ever reproduce, on a large scale, the essential features of Grecian physical training; for the same reasons that forbid us to look for the rise of a new Sparta or a second Athens.

Grecian physical training was of an empirical nature; for the Greeks, even the best of them, had next to no scientific knowledge of the human body. Plato's physiology is clotted nonsense. Aristotle looked upon the muscles as mere padding for the bones, not suspecting them of being the organs of motion, and held that the chief function of the brain was to cool the heart. But the Greeks were rare empiricists, and saw with wonderful clearness what lay within the range of their unaided vision. Having insight and experience, loving beauty of form, being favored of Heaven as to climate and leisure, their gymnasiarchs and athletic trainers produced types of manly beauty and health which have never been surpassed. The dominant note in the history of the Middle Ages is one of warfare. Education, accordingly, was conceived and carried out with a view to what may be called the technical preparation of the young ecclesiastic or noble for the post of under-officer, either in the cohort of a Lord Spiritual or of a Lord Temporal. Though very much has been done in the last hundred years towards making exact sciences out of the art of war and the art of healing; the art of teaching is still, in the main, characterized by empirical methods, especially among English-speaking peoples. This is particularly true of bodily education.

The mediaeval and British types of physical training resemble the Grecian in being natural growths, which smack of their native soil rather than manufactured productions, bearing the tool-marks of their designers and artificers. It is characteristic of modern systems of gymnastics that they have been devised chiefly for remedial or pedagogical ends; and, furthermore, that we have comparatively full and trustworthy accounts of the men and measures whereby their rise and development have been determined.

Enthusiastic worshippers of classical antiquity and writers on education — especially at such times as the Renaissance, the Reformation, and the revolt of the Realists against merely humanistic training in the last quarter of the eighteenth century — have shown a marked tendency to laud and magnify the physical training of the Greeks. Indeed, did time permit, we might readily trace the influence of that training upon some quite recent forms of school gymnastics, since there have been repeated attempts, in Germany, to domesticate the exercises of the Grecian *Pentathlon*, namely, running, leaping, spear-throwing, casting the discus and wrestling. Still the fact remains that no general or very considerable revival of Greek athletics and gymnastics has occurred within five hundred years. Though mailed knights, and the martial exercises which they most affected, have been knocked out, so to speak, by the anathemas of the Church, and other more modern explosives, the code of the soldier and the gentleman is still colored by the traditions of chivalry which favor such bodily accomplishments as riding, hunting, fencing and dancing. The "fagging" of British school-boys is a survival from the period when the training of the young noblemen in "courtesy" included the performance of many tasks that we hold to be menial. Many of the customs of German university students, especially those which regulate their duelling, are re-

mindes of the times when swordsmanship formed a necessary part of every gentleman's education. In the sixteenth and seventeenth centuries and late into the eighteenth, a class of special schools, termed *Ritterschulen* or *Adels-Akademien*, were maintained in various parts of Europe, but particularly in Germany, for the education of the sons of the nobility. In such schools instruction in riding, sword-play, dancing and leaping was regularly given; swimming was much practised, and sometimes wrestling.

Although the reformers, Luther, Melancthon and Zwingli, urged the revival of gymnastics as a part of the education of all classes of youth, it was not till the last decades of the last century that any considerable attempt was made to systematize and enforce gymnastic training in Germany. The attempt was made by Basedow, who was a leader in the educational reforms instituted by the so-called Philanthropists, who strove to carry Rousseau's views in education into effect, or, in other words, "to manage it so that the training of the mind and body shall serve to assist each other." The pupils in the Philanthropium, which Basedow established at Dessau, in 1774, were taught wrestling, running, riding, and dancing, besides carpentry and wood-turning. They were also taught the elements of human anatomy and physiology. The Philanthropists employed both gymnastic and industrial exercises in their efforts to secure the physical training of their pupils. Therein they showed more wisdom than do most of the advocates of manual training among us, who neglect the training of the trunk and limbs for the sake of the hand and fingers. The so-called "Dessau Pentathlon" consisted of running, jumping, climbing, exercises in balancing, and carrying weights. Some of our Young Men's Christian Association authorities have recently promulgated a "Pentathlon," which is a most un-primitive Christian proceeding.

In 1784, Salzmann, who had been one of Basedow's assistants at Dessau, established a Philanthropium at Schnepfenthal, near Gotha. The three most eminent names in the list of men identified with the revival and upbuilding of German gymnastics are those of Guts Muths, Jahn and Spiess. Each was a teacher and writer. Jahn was an agitator and popular leader in addition. Guts Muths lived from 1759 till 1839, Jahn from 1778 till 1852, and Spiess from 1810 till 1858. Schnepfenthal has been termed "the cradle of German Turning." Guts Muths labored here as teacher from 1785, till his death. Soon after Guts Muths entered Schnepfenthal, in 1785, Salzmann intrusted him with the direction of the five exercises brought from Dessau. "All that I found out from ancient usages," says Guts Muths, "from the historical remains of earlier and later antiquity, all that reflection and sometimes chance offered to me, was brought forward for the sake of amusing experiments. Thus the chief exercises increased. Thus originated, after seven years' experiments, in the first edition of my 'Gymnastics for the Young' (1793), my first attempt to call attention to a subject that had been quite forgotten." His *Gymnastik für die Jugend* was the first German manual of gymnastics. Guts Muths did much to prepare the way for Jahn, the "Father of Turning," and Spiess, the "Founder of German school gymnastics and the creator of gymnastics for girls." Inspired by the example of Guts Muths, many private and a few public teachers introduced gymnastics into their schools. In 1799, Nachtgall, a follower of Guts

Muths, established a private gymnastic institute in Copenhagen. The Danes were the first people in Europe formally to adopt the new gymnastics for use in schools and the army. Ling, the founder of Swedish gymnastics, while a student in the University of Copenhagen (1799-1804), had his first lessons in gymnastics from Nachtgall.

Guts Muths, at first, defined *Gymnastik*, a term which was rejected by Jahn but retained by Ling, as "work in the garb of youthful pleasure or merriment." Later he defined gymnastics as "a system of exercises having bodily perfection for their aim." Jahn worked mostly in the spirit of Guts Muth's first definition, Ling in the spirit of the second. It is quite possible, too, that Ling received some impulse towards his laborious studies of the laws of bodily movements from the following utterance of Guts Muths: "I know well enough," says the latter, "that a genuine theory of gymnastics should be based on physiological principles, and that the practice of every single movement should be governed by a consideration of the individual peculiarities of the body." Guts Muths divided "pedagogical physical exercises" into three departments: (1) gymnastic exercises, (2) manual training, and (3) youthful plays. His distinctively gymnastic exercises were: free and pole jumping, short and long-distance running, casting the stone, wrestling, climbing, "balance-movements," lifting and carrying of weights, dancing and marching movements.

That gymnastics, under the name of *Turnen*, became a popular institution and a potent factor in national development, was mainly due to Jahn, a much more aggressive man than the quiet "philanthropist" of Schnepfenthal. Jahn's strong and rugged nature, and restless, passionate spirit, qualified him for popular agitation and leadership in the troublous years between the battle of Jena, in 1806, and the Prussian War of Liberation, in 1813. Jahn seized the idea of making bodily training a force in national regeneration and education, and dreamed and wrote and plotted for a free and united Germany. In 1810, when he was a teacher of boys in one of the city schools of Berlin, Jahn began his career as a gymnasiarch by accompanying a few of his pupils into the woods and fields for the purpose of engaging in youthful sports and exercises on holiday afternoons. His first *Turnplatz* was opened in the *Husenheide*, a pine forest in the outskirts of Berlin, in 1811. The movement became extraordinarily popular, and young and old flocked to the gymnastic ground. The Jahn Turning was rudely systematized; but slight use was made of "free movements," which were first given a prominent place in German gymnastics by Spiess. The Turners were organized in squads, according to their age and strength. Feats in agility, strength and endurance were performed by Jahn's assistants, called *Foreturners*, and the rest of the squad took turns in "following suit," to use a term common among New England boys. Jahn employed the exercises of Guts Muths, and, with the help of his foreturners, devised many new forms of exercise and apparatus. Prominent among the latter are the horizontal and parallel bars, and certain machines to facilitate exercises in climbing. The Turners were active in the successful uprising against the French in 1813, so that Turning became more than ever popular, throughout Germany in 1814 and 1815. During the political troubles which arose after the War of Inde-

pendence, Jahn and the Turners were denounced as liberals and enemies of the State. In 1819 the turning-grounds throughout Prussia, and in most of the other German States, were closed by the police. Jahn was imprisoned from 1819 till 1825; but he lived to see gymnastics introduced into the Prussian schools, by order of the King, in 1842; and before his death, in 1852, Turners' societies were once more in a flourishing condition throughout Germany.

At the present day German gymnastics include the popular gymnastics of the *Turnvereine*, school gymnastics, and military gymnastics, the latter being a modified form of school gymnastics. School gymnastics include free movements, light gymnastics, or exercises with light apparatus such as wands, dumbbells, and clubs, and *Gerütbungen*, or exercises on the more difficult gymnastic machines. Spiess introduced "class" and "order" gymnastics, thereby making it possible for the ordinary teacher of a school class to teach gymnastics to all his pupils, in the same way that other branches of study are taught. In the army and in the schools, exercises of all sorts are executed by the class or division at the word of command. In the *Turnvereine*, free and class gymnastics are also conducted in the manner alluded to above; though in heavy gymnastics the foreturner feature is retained. Both Germans and Swedes have outgrown the childish practice, so common in America and England, of teaching gymnastics by means of memorized and musical drills. Indeed, I doubt if German or Swedish teaching was ever hampered by such inept and ineffectual methods. Special normal schools for the training of teachers in gymnastics exist in most of the German States; and a large proportion of the elementary and secondary schools are provided either with a well-equipped gymnasium, *Turnhalle*, or else a *Turnplatz* out of doors. Many schools have both. In many of the larger and higher schools, special teachers of turning are installed; while in the elementary schools, for the most part, gymnastics are taught by the class-teachers. But usage in this regard is not uniform.

School and military gymnastics have grown to a large extent out of popular gymnastics, or *Volksturnen*, which still retains its place as the most distinctive branch of German physical training. The union of the German turning societies is known as the *Deutsche Turnerschaft*, an organization of some thirty years' standing. On January 1, 1891, out of 4,763 turnvereine in Germany and Austria-Hungary, 4,252, in 3,603 localities belonged to the Turnerschaft, whose total membership numbered 421,000 men and boys over fourteen years. Of the total membership (which amounts to 1.6 per cent. in a population of more than twenty-five millions), more than one-half are classed as "active turners" and ten per cent. as skilled gymnasts or "foreturners." In 1880, the Turnerschaft numbered 170,315 members of whom 86,159 were active turners. It is almost as usual to find turnvereine among Germans in foreign lands, as to find cricket and foot-ball clubs among British colonists. Turning societies flourish in the United States, Brazil, China and Australia, as well as in all European countries. In the United States, the principal association of the turners is the North American Turnersbund, which has a membership of over 35,000. It may be noted in passing that the Turnersbund, which dates from the revolution year of 1818-19, is much more highly organized for social and political purposes than the German turners ever were; that it has been in-

fluent in securing the introduction of physical training into the public schools of Kansas City, Cleveland and Chicago; and that it maintains a larger number of gymnasia, and a fuller and more competent corps of teachers of gymnastics than do all our colleges put together.

Having spoken at length, in a previous lecture of Ling and his work, I shall confine myself, in this connection, to a rather summary treatment of the Swedish system of educational gymnastics, foregoing all consideration of the Swedish *Skulgymnastik*, or movement treatment. The Swedish *Friskgymnastik* differs so widely as to its origin, aims and methods from the German *Volksturnen*, that the two are rather to be contrasted than compared. Popular gymnastics have never occupied the foreground in Sweden, and have assumed extremely little prominence, even in the background, till within rather recent years. In Norway, popular gymnastics are only semi-Swedish. In comparing Swedish and German school gymnastics, the distinction between an artisan's kit of tools and an instrument of scientific precision suggests itself. Swedish gymnastics owe their distinctive features of simplicity of form, compactness and balance of parts, finish and precision of method, to Ling and his successors at the Royal Central Gymnastic Institute in Stockholm, which has been maintained by the Crown as a normal school, for the education of civilian and military teachers of gymnastics since it was opened, at Ling's instance, in 1814. Ling's principal writings are poetical; but he had more of the patient, critical, scientific spirit than Jahn, and did his best to discover the physiological and pedagogical laws which should underlie every rational scheme for the bodily training of children and youth. His natural impulses, and the exigencies of his position as an official teacher of teachers and of military cadets, combined in leading Ling to adopt simple, direct and orderly measures. He made use of both free and class exercises before Spiess introduced them into German gymnastics. Apparatus gymnastics, though regularly employed by the Swedes, are given less prominence than is accorded them by the Germans. Certain gymnastic machines which are favorites with the Swedes are not used in Germany, and *vice versa*. Gymnastic games and fencing are employed both by Swedish and German teachers of school gymnastics. Much less care and attention have been given in Germany than in Sweden to physiological considerations, in the selection and arrangement of gymnastic movements; therefore the Swedes reject many forms of exercise as useless or injurious which pass muster in Germany. For example, the Swedes discard exercises that tend to constrict the chest, those that require the breath to be held, and those producing continued pressure on the larger vascular or nerve trunks. One of their most stringent rules is, that all movements should help and not hinder full, free and regular breathing. Swedish gymnastics surpass all other forms of pedagogical gymnastics, in the care taken, not only in co-ordinating the exercises belonging to a single "day's order" with regard to each other, but also with regard to the "day's-orders" which have been practised, and the "day's-orders" that shall follow. By means of the "day's order" or "table" and the principle of "gymnastic progression," which they alone have worked out and adopted, the Swedes are enabled to order and vary their school gymnastics, from day to day, from month to month, and from year to year,

in a graded series. By this means continuity is secured in the instruction; and the pupils, of whatever age or condition of health, are advanced from simple, easy, and absolutely safe exercises, to those that are complicated, difficult, or comparatively dangerous. Class-leaders and memorized drills have no place in instruction of this kind. All exercises, whether by a full class or by a squad, are executed at the word of command. Continuous, progressive, and comprehensive gymnastic training cannot be secured by mere imitation of a leader, or by executing memorized exercises over and over again. Change and variety are necessary, and must be had. They are best secured in school gymnastics, by recognizing the laws of physiology and by following the principles of sound teaching.

Compared with teachers of gymnastics in any other country, those of Sweden are a small and highly trained corps. From its inception, the majority of the pupils of the Central Institute have been young officers in the army and navy, so that teachers of gymnastics in Sweden hold a better social position than elsewhere. Under special circumstances one may, by passing the required examinations, be licensed to teach without taking the course at the Central Institute, a course be it said, more extended, comprehensive and severe than is the case in any other European normal or military gymnastic school. The influence and traditions of the Central Institute are paramount in all branches of Swedish gymnastics, and have made them what they are.

Hitherto, school gymnastics in Switzerland, Austria, Belgium, Denmark, Russia, Italy, England, and even in France have followed or resembled German school gymnastics in the main; but in France, Denmark, England and Russia a tendency to adopt or approximate towards Swedish methods has declared itself, recently. In my opinion, the Swedish systems are better adapted to the needs of school children, between the ages of seven and fifteen, than any other. For boys above fifteen and collegians—at any rate in England and America—I am inclined to think an admixture of German forms of exercise will be found advantageous; but I would have them grounded in Swedish gymnastics to begin with.

Speaking broadly, the muscular and nervous tissues, well termed the "master tissues," constitute the executive or working mechanism of the body; and the chief function of all the other tissues of the body is to serve either as their purveyors or scavengers. The structural integrity and functional power of the purveyor and scavenger tissues are indirectly promoted by muscular activity; but the most important effects of muscular exercise are, (1) the attainment or maintenance of normal size and strength by the master tissues, and (2) the acquirement of correct and economical habits of neuro-muscular action. The ends of physical training, then, are hygienic on the one hand and educational on the other. No comprehensive system of physical training can be considered safe or rational in which these ends are not clearly recognized and intelligently provided for—through the adaptation of its exercises to the varied and varying wants and requirements of the individuals to be trained, in respect to their sex, age, strength, mental capacity and calling in life. The results which should be secured by such a system are briefly these: Erect and graceful carriage of the head and trunk; a broad, deep, and capacious

chest in which the heart and lungs, developed to their normal size and strength, shall have free, full and regular play; square shoulders; a straight back; fully-developed and well-rounded limbs and the power to execute with ease, precision, and economy of force, such movements as are involved in the simpler exercises of strength, speed and skill, and in ordinary gymnastic and athletic feats.

In general, we may say that the Grecian gymnastics and athletics, and the martial exercises of the ancient and mediæval Gauls and Teutons were of a character to affect chiefly the fundamental or earliest developed neuro-muscular mechanisms,<sup>2</sup> which constitute "the coarse adjustment" of the body. The more massive bodily virtues of strength, endurance and speed are promoted by popular sports; whereas dexterity, address, sleight-of-hand, quickness and accuracy of eye and hand require more specialized and complicated forms of exercise for their development. In other words, British sports are insufficient for the purpose of giving a complete training to the fundamental and accessory groups of muscles, and require to be supplemented by such drill as is afforded by the systematic gymnastics of the Swedes and Germans. For purely educational ends no system of physical training has yet been devised which is equal to the Swedish school gymnastics. American physical training will remain a thing of shreds and patches, unless the promoters and governors of our educational institutions shall set themselves to learn to apply the teachings of science and experience with regard to the nature, scope and results of physical education.

### CONTRIBUTIONS TO THE STUDY OF CHOREA, WITH SPECIAL REFERENCE TO ITS CONNECTION WITH HEART DISEASE AND RHEUMATISM.<sup>3</sup>

BY DR. S. G. WEBBER.

I HAVE been very much interested in this subject. I cannot, however, undertake to add anything to the general review of the subject. I have not had time to look over the cases of chorea which I have seen, but my impression is that heart disease and rheumatism have appeared less frequently in my experience than in that of some others. I think it has been comparatively rare for me to find that cases of chorea have had clearly defined attacks of articular rheumatism. Two very interesting and rare cases have come under my observation, in which the chorea seemed to supplant the rheumatism. In both cases the child had an attack of acute articular rheumatism. After a short time the choreic symptoms appeared. The rheumatic affection then diminished in severity. I think the joints were less swollen. The chorea in both cases was very severe. It was necessary to put sides to the beds to prevent the patients from throwing themselves out of bed. The attack was of moderate duration, and in both cases as the chorea passed off,

<sup>1</sup> Presented at the regular meeting of the Boston Society for Medical Improvement, Monday, November 2, 1891.

<sup>2</sup> For a fuller discussion of the effects of exercise on the nervous system see "On the Physiology of Exercise," this JOURNAL, March 23 and April 7, 1887, and "General Exercise," *Hare's System of Practical Therapeutics*, vol. I, 1891, by the writer.

the rheumatism reappeared, and the joints again became swollen. The cases were very singular. Both of them had heart disease. It is only a few months since I heard from one of those cases and the heart affection still persists. It was, I suppose, organic in both cases. In one I know it was. I think the rheumatism acts simply as a predisposing cause, like any other influences which lower the child's power of resistance.

I had at the City Hospital a very peculiar case. There were no choreic movements in the child, but the heart was irregular. I put the child on arsenical treatment as if it had chorea, and the heart became steadied and the affection entirely disappeared. It seemed to me as though it was an attack of chorea without general muscular disturbance, but simply with heart affection. That is the only case of the kind I have seen.

BY DR. F. C. SHATTUCK.

The English views on the subject of the relation of chorea to rheumatism and heart disease are well known. The English statistics vary very widely, anywhere from twenty per cent. to over fifty per cent. of cases with such association, and as far as I know, the subject has received more attention from that nation than from others. Fagge says that Dr. Bright taught years ago that these affections are related. He also says: "Of 163 cases compiled by Mr. Halstead (unpublished). 53 had had rheumatic fever or distinct pains in the limbs, believed to be rheumatic, and in 35 of them the rheumatism preceded the chorea by less than six months." The Guy's Hospital cases have been very carefully collected, and I think we should attach great value to the statements of such men as Fagge and Pye-Smith, who doubtless exercised much care in determining whether there was or was not a history of rheumatism. The causes for wide variation are not far to seek. Has rheumatism been present or not? Is endocarditis or its legacy present in a given case? These are two points as to which observers may very well differ. In rheumatism we have cases with transitory murmurs, which are attributed to endocarditis because of this association. If there were not rheumatism we should often class these murmurs as dynamic. That there are cases of endocarditis in which there is no murmur, is a fact of which we have *post mortem* evidence. So that the presence or absence of an endocarditis is not always an easy matter to determine, even by the most skilled observers.

It seems to me very important that this matter should be brought up as to the relation, if there be one, of these affections; and it is of comparatively recent years, I think, in this community, that much importance has been attached to the endocardial murmurs in connection with chorea. Certainly I was taught as a student that such murmurs are nearly always functional in character. That is probably a practical error, and one of importance with regard to treatment.

Dr. Osler studied this question in connection with the chorea cases which came to the Philadelphia Orthopaedic Institution some years ago, and his conclusion was that any murmur in a case of chorea should be treated exactly as if it were indicative of an endocarditis.

The difficulties of the subject are very great. In

the first place, we do not know what rheumatism is. In the second place, we do not know what chorea is, so that to establish what is the exact connection between the two is not an easy matter; but the number of cases in which there is an association is altogether too large to be simply a matter of chance. It seems to me that much importance is to be attached to one point, namely, that in almost every fatal case of chorea, vegetations are found upon the cardiac valves. The patients don't die from the endocarditis. They die from the chorea, or from some intercurrent disease, but the valves are found diseased. Of eighteen fatal cases in Guy's Hospital, in seventeen the valves were diseased. I would not state positively, but it is my impression that in some of these fatal cases in Guy's Hospital the apparent exciting cause of the chorea was a fright. How fright is to set going an endocarditis is not an easy matter to understand; but there is the fact, the valves were found diseased. As I listened, some years ago, to Dr. Cheney's paper on the cure of some cases of chorea, or of choreiform movements, by the correction of refractive errors, the question came into my mind, may not chorea be a symptom rather than a disease?

Again, it seems to me that the paper of Dr. Morris Lewis, published some three or four years ago, is of interest in this connection. Dr. Lewis, I think enlarging some investigations of Dr. Weir Mitchell, studied very carefully the time of onset of a large number of cases of chorea, taking them from the records of the Orthopaedic Hospital in Philadelphia, and he states that far the largest number of cases originate in March. Then he studied in the Pennsylvania Hospital the records of a large number of cases of rheumatism, and he found that decidedly the largest number of those cases occurred in April. He also studied the meteorological records and found that the chorea curve was almost exactly parallel with the storm-centre curve, that is, the storm-centre within four hundred miles of Philadelphia, so that while chorea came at the time of the storms as it were, rheumatism came a month later.

BY DR. MORTON PRINCE.

The great difficulty with statistics in regard to previous attacks of rheumatism in cases of chorea, is the laxity with which the evidence in favor of previous attacks of rheumatism has been collected. It has varied from an insignificant amount, say six per cent., by Hermann, up to 85 per cent., by Hughes and Burton Brown. Of course, this great difference must depend very largely upon the personal factor. But besides the mere occurrence of a previous attack of rheumatism, there is another factor which, it seems, must be taken into consideration in determining the existence of a causative relationship, and that is the time that has elapsed since the attack of rheumatism, and previous to the outbreak of chorea. So far as I have been able to look into the subject, very few of those who have given statistics have stated the length of time that has elapsed. It is perfectly evident that the value of any collection of cases must depend largely upon this factor. If, for example, in a case of chorea following rheumatism, an interval of six months had intervened between the attacks of the two diseases, that case would be of less value as evidence in favor of the rheumatic origin of chorea than one in which the chorea had occurred coincidentally with, or had followed within a few days,

the rheumatism. Most statistics do not give any information on this important point. Therefore the value of most statistics, to my mind, is greatly weakened by the failure to note the time interval. More important are the cases, of which there are quite a number on record, in which the chorea has coincided with or followed immediately upon the rheumatism.

Thus Herringham has reported a series of cases, eighty in number, in which he found a previous history of rheumatism in twenty-one. In six of these there was an immediate connection, that is, in two the chorea developed coincidentally with the rheumatism, and in four it followed immediately after. It seems to me that such cases offer a very strong argument in favor of a casual relationship between rheumatism and chorea. Although the number of cases of this sort is small in proportion to the cases where the time interval has been long, still the number is absolutely quite large, and is of much greater value as evidence than a very much larger number of cases of the other kind.

But granting the relationship, as I personally do, one of the most important questions is, what is its nature? This is the most difficult question of all to answer. It seems to me that to understand it at all we must take a broader view of the question, and consider all the conditions under which chorea has been found to occur, and if we shall do this we shall find that all the evidence points to the conclusion that chorea must be looked upon as a symptom-complex, as a group of symptoms dependent upon a condition of the cerebro-spinal system, which anatomically is not known yet, but which may be produced by a very large number of different pathological conditions. In this respect it may be likened to convulsions. A convulsion is a complex group of symptoms which may be due to focal lesions in the brain, or to more diffuse cerebral disease. It may be due to poisoning from lead, or to "blood poisoning," as in uræmia; it may be due to reflex irritation, as from wounds and intestinal diseases of children; it may be due to the poison of contagious diseases, as in scarlet fever; or it may be due to unknown changes in the brain, as in idiopathic epilepsy; and so with chorea. Chorea has been found to exist under a great many different conditions. It occurs in the course of rheumatism and in the course of heart disease. It is known to occur frequently after fright, in fact, Hermann, who places the number of cases in which rheumatism has existed as low as six per cent., claims to have found fright in forty-two per cent. of the cases. It has been known to occur in iodoform poisoning, as in a case reported by Demiere. Errors of refraction seem to be an exciting cause in some cases; for Colburn found refractive errors in 39 out of 51 cases. There was no return of the symptoms in any of these cases after correction of the errors, and the patient had become accustomed to the new conditions. Circumcision of an adherent prepuce cured the symptoms in a case reported by Leonard, and Jacobi reports a case cured by operation for the relief of nasal irritation. Like convulsions, chorea has also been observed in the course of infectious diseases; and Handfield Jones and others have met with it as a result of pregnancy. There is also a well-known type known as hereditary or Huntington's chorea, which, although having a different course and clinical history from the ordinary form, yet resembles it closely in the motor symptoms. Other cases seem to be entirely without

ostensible cause, or to be idiopathic. Thus the conditions under which chorea occurs, show a very remarkable parallelism with those under which convulsions are met with.

Looked at from this broad point of view, the facts, as a whole, would seem to require that chorea should be regarded as a group of symptoms which may be due to a large number of causes, of which one is rheumatism; and, it seems to me, that the connection between the two is to be found in the poisoning of the system or impairment of nutrition, rather than in an embolic process. I am rather sceptical regarding the embolic nature of chorea, because I think the clinical and pathological evidence points to the fact that the spinal cord in a certain number of cases is affected as well as the brain. We must remember that in chorea one of the symptoms which is not very infrequently met with is paralysis, and amongst the paralyses, paraplegia has been observed. Now it is very hard to believe that, when paraplegia occurs, it is due to cerebral and not to spinal disease. In fact, the autopsies have shown in some cases the presence of hyperæmia and minute hemorrhages into the spinal cord as well as into the brain; and therefore, as a direct factor, I cannot myself accept the notion that cerebral embolism plays a very important part. In the autopsies I think the most frequent changes have been found to be not embolism, but hyperæmia and extravasation of blood and changes in the cells.

BY DR. W. N. BULLARD.

I have now for many years kept careful records of cases of chorea, with special reference to troubles of the heart in connection with this disease. These cases have been almost all very carefully examined by myself, and the results may be considered those of personal observation. Before coming here, I looked over one hundred of these cases, and I will state the results.

The first point which I noted was the presence of rheumatism in the parents — practically all my cases were children; but of one hundred cases in which this fact was noted, one or both of the parents had had rheumatism in 28 cases; in three additional cases it was doubtful, but had probably existed. Only those persons are counted as having had rheumatism in whom decided symptoms existed. In four cases it was found not in the parents but in the grandparents.

Of the patients themselves, out of 100 cases, 17 had articular rheumatism, and four rheumatic fever (21 severe cases); nine had pains and more or less doubtful symptoms; while the rest (70) were recorded as having never had rheumatism. In several of these cases the rheumatism immediately preceded the chorea.

The heart was carefully examined, and I tried in all cases to distinguish as far as was possible between organic disease and functional disease. I found that there was probably severe valvular lesion or endocarditis in 27 cases, and slight cardiac trouble in 16 cases. There was marked cardiac irregularity in eight cases, of which four had valvular trouble and were counted among the lesions; the other four were not counted. Adding them to the slight affections (though some of these were probably due to valvular trouble), we have 17 cases in which the heart was not absolutely normal, in 27 of which, at least, we had to deal with organic lesions, and probably in many of the other cases there was some slight organic difficulty.

A systolic souffle, heard all over the cardiac area, probably due to organic disease, was found in 10 cases; a systolic souffle, limited to the apex, occurred in 12; a systolic souffle over the aorta, evidently organic, occurred in one; and in 10 there was a systolic souffle loudest at the base and possibly anemic. There were two cases of aortic disease, one of acute endocarditis occurring with the chorea while under observation.

Is the cardiac affection apt to occur previous to or with the first attack of chorea? Or do we find it more frequently occurring for the first time when the patient returns with another attack? Out of the 27 cases of severe heart trouble, 15 had chorea for the first time; in six cases it was found during the second attack (these patients were not seen during the first); in three cases we have no record of the number of the attacks; and in three it was found in attacks later than the second. In two cases it was recorded as not present in the early attacks, while it was found the time of a later attack.

In eight cases the patients had had rheumatism severely previous to the time seen, and in five others slightly; in two cases there was no record upon this point; in 12 no rheumatism had been noticed.

The date of the precedence of the rheumatism or its time in relation to the choreic attacks seems to me a matter of small importance. There are many cases in which acute articular rheumatism or endocarditis precedes chorea, sometimes by a long and sometimes by a short period, and many others in which these affections are found coinciding with or following a choreic attack. A person who has once had an attack of acute articular rheumatism or rheumatic fever, is liable to rheumatic manifestations at almost any time, when predisposing causes exist. Therefore, in discussing the evidence as to the existence of a connection between chorea and rheumatism, it does not seem to me to be necessary to show a direct time connection between the two. As a matter of fact, in many of my cases the rheumatic symptoms did immediately precede or coincide with the chorea.

Chorea seems to me to be simply a symptomatic trouble in the sense in which this term has just been defined. It is due to a hyperirritability or irritability of certain portions of the central nervous system. It may be produced by a variety of causes. It is specially liable to occur in the children of neurotic parents, and in those who have a congenital neurotic constitution. In a certain number of my cases more than one child in the family had chorea; in many the parents have neurotic troubles. Again, a large proportion of the cases of chorea occur in children who are extremely anemic, whether the anemia be due to rheumatism or to other causes.

Two of the principal predisposing causes of chorea are a *neurotic disposition* and *anemia*. I have no question that rheumatism is connected with chorea.

BY DR. PHILIP COOMBS KNAFF.

Some time ago I tabulated the cases of chorea which had come under my observation, with the intention of reporting the results of such a tabulation. I have since revised the tables, and brought them up to date. I had noted the relation of chorea to the time of year, and I will ask permission to report briefly my result. In five years from May 1, 1885, to May 1, 1890, 112 new cases of chorea, out of a total of 2,398

new cases, presented themselves at the nervous outpatient department of the Boston City Hospital. I have arranged them by months as follows:

Months.	1885-86	1886-87	1887-88	1888-89	1889-90	Total.
May . . . . .	8		1	1	3	20
June . . . . .	4		1	4	7	21
July . . . . .	5		3	1	5	19
August . . . . .	3	6	0	2	4	15
September . . . . .	3	1	0	0	3	7
October . . . . .	0	1	0	2	3	6
November . . . . .	2	1	0	1	1	5
December . . . . .	2	1	1	1	0	5
January . . . . .	3	0	0	1	0	4
February . . . . .	4	2	2	0	0	8
March . . . . .	5	6	6	3	3	23
April . . . . .	1	0	2	3	3	9
	40	32	19	19	32	142
Total cases . . .	421	483	461	495	538	2398

Solid, cases presenting themselves at hospital during month (142).  
Dotted, cases beginning in month (138).

Of these 142 cases, I was able to determine the date of onset in 138, but, of course, not with absolute accuracy. The result was as follows:

January . . . . .	11	August . . . . .	10
February . . . . .	11	September . . . . .	4
March . . . . .	22	October . . . . .	9
April . . . . .	13	November . . . . .	4
May . . . . .	20	December . . . . .	3
June . . . . .	17		
July . . . . .	17		
			138

These results agree tolerably with Weir Mitchell's. It will be seen that in March, May, June, July and August, the number of cases presenting themselves at the hospital was above the average; in March, April, May, June and July the number of attacks was above the average. In both cases there is a curious decline in the month of April. One case reported an attack every spring from the age of five to the age of sixteen, then an attack in the spring at the age of nineteen. The cases of chorea have grown less, in spite of an

increase in the whole number of patients, until the year 1889-90, when there was an increase. Some cases have certainly followed the epidemic of influenza; perhaps that explains the increase.

Solid line, boys. Dotted line, girls.

My statistics were originally based on 80 consecutive cases seen by me in out-patient service. I have taken only the cases that came to me as new patients, omitting all cases of relapse, which had originally been under the care of my colleagues, and all cases handed down by them. I have since added 15 other cases, which, oddly enough, materially alter my percentages. Cases of chronic chorea of adults, and chorea due to gross brain lesions are, of course, excluded. There were 39 boys and 56 girls. Sixty-nine came first during the first attack, 18 during the second, four during the third, two during the fourth, one during the fifth, and one during the twelfth. The ages were as follows:

Age.	Girls.	Boys.	Total.
3	1	0	1
4	3	0	3
5	1	0	1
6	8	1	9
7	3	2	5
8	1	3	4
9	1	4	5
10	11	4	15
11	3	3	6
12	6	4	10
13	1	3	4
14	2	2	4
15	2	0	2
16	2	0	2
17	2	0	2
18	2	0	2
19	1	0	1
26	1	0	1
56		39	95

The influence of puberty is certainly not apparent.

Like every physician who has seen much of chorea, I have occasionally met with cases associated with acute articular rheumatism and endocarditis which harmonize with the English views, but I have doubted the traditional relation, and I have certainly failed to note it in the majority of my cases.

Rheumatism is certainly a vague term and its use often recalls the German couplet:

"Was man nicht diagnostizieren kann  
Das heisst man als rheumatisch an."

If there be any relation it must be with acute articular rheumatism, not with vague pains of unknown causation often called rheumatic. My observations

show that the relation is distinctly less frequent than in some other series of collected cases. In eight cases there had been acute articular rheumatism, in five of which the rheumatism and chorea were closely connected in point of time. Four of these cases of rheumatism occurred in the last 15 cases. Five of the eight cases came during the first attack of chorea, two during the second, and one during the twelfth. In 25 other cases there were pains, which were variously described as follows:

"Rheumatism"	1
Swollen ankle, not painful	1
Pain in knees, coming on with attack	2
Pain in knees	2
Pain in feet before attack	1
Pain in joints	2
Pain in back and legs	1
Aching in legs	1
"Growing pains"	2
Pain in hips toward end of attack	1
Pain in bones	1
Pain in muscles	1
Backache	1
Pain preceding attack	1
Pain during attack	1
Pains	4
25	

Such pains are too vague in character to be of importance, and they have no relation to acute articular rheumatism. In the majority of cases the patients made no complaint of them, and their existence was brought out only by questioning.

In 32 cases the patients had had scarlet fever, and in two cases chorea followed scarlet fever immediately. In three cases chorea followed influenza.

Such figures, showing acute articular rheumatism in less than ten per cent. of the cases, furnish a strong argument against the old theory that rheumatism was the cause of chorea. Nevertheless, rheumatism seems commoner in patients with chorea than with other patients. The statistics are uncertain, but I have collected from the reports of the Children's Hospital from 1885 to 1890 inclusive, some figures. Out of 2,095 cases admitted to the hospital in six years, 23 were admitted for rheumatism, 37 for chorea. In the three years, 1888, 1889, and 1890, out of 4,430 out-patients, 16 had acute or sub-acute rheumatism, 84 chorea. The percentage of rheumatism is much below that seen in my cases of chorea, less than a half of one per cent., instead of eight per cent.

The cardiac disturbances in chorea are of various sorts; endocarditis is, of course, the most important. In 16 cases cardiac irregularity was noted; in five of these cases the irregularity was associated with a cardiac murmur; in another case it was clearly due to the excessive use of tobacco. The figures are doubtless too low, as I probably failed to note it in a few cases. In six cases the cardiac sounds were rough, booming or tumultuous. In three cases an anemic murmur was noted in the neck; it may have existed in other cases. In 20 cases there were endocardial murmurs, as follows:

Systolic apex	12
Systolic at base	2
Double at apex	2
Systolic apex, with enlargement	1
Systolic base, with enlargement	1
Double base, with enlargement	2

20

In five of these cases there was acute articular rheumatism, in five others various pains. Of the four cases

with enlargement only one had had rheumatism, another had had pains. Fourteen came during the first attack, three during the second, two during the third, and one during the twelfth. A heart murmur, however, is not necessarily an indication of endocarditis, or even of valvular disease.

Such is the result of my observations on chorea. It is probable that acute articular rheumatism and perhaps endocarditis, are commoner in choreic patients than in patients with other affections, yet three-fourths of the cases of chorea have neither rheumatism nor endocarditis. It is unwarrantable, therefore, to ascribe to acute articular rheumatism the chief causal influence on chorea. Other factors, the neuropathic taint and overwork in schools, are of some importance. It may be that chorea is an acute infectious disease. It is probable, moreover, that what is now regarded as one affection, the chorea of Sydenham, may eventually be divided into several distinct diseases, and arising from various causes: overwork, fright, irritation, infection? rheumatism, or debility. Scarlet fever is certainly much commoner as an antecedent than acute rheumatism.

BY DR. J. J. PUTNAM.

I think the study of the relationship of different diseases is a very fascinating one, and that we should not be deterred by the apparent want of resemblance from seeking real kinship between them. I agree with those who hold to the relationship of chorea to many other conditions, but inasmuch as the relationship between chorea and rheumatism is closer than that between chorea and most other forms of disease, we are likely to learn more by studying it.

There is one class of cases not always enough alluded to, and that is those cases in which chorea precedes rheumatism. In the co-operative investigation of the English physicians that was found to occur in two per cent. (as cited by Sturge). I have seen one or two cases of that sort. In one case (a neurotic child of neurotic parentage) chorea came on when the patient was quite a young boy, and at that time he had a murmur which I believed to be functional. The murmur was diastolic and was heard on the left side of the sternum. He had had no rheumatism whatever. Within the last year, he being now about twenty years old, he had quite a sharp attack of rheumatism, and this murmur was found to be increased. The heart is much enlarged and he suffers from various symptoms of cardiac trouble.

Dr. Osler induced his cases of chorea to come back, and he examined quite a large number of them, and found in a large proportion of them murmurs which had not been noticed at the time of the first examination, but had developed later.

A few words as to the relation of chorea to the weather. I find in looking over the Massachusetts Hospital records for the years covered by Dr. Lewis's report, that the number of cases beginning in the summer was very small, while there was a comparatively large number beginning in October and the largest of all in March. Dr. Lewis's corresponding months were September and April I believe. The cases beginning in October could hardly be attributed to the debilitating effects of school-life, and in general I doubt whether debility by itself leads to chorea.

The relation of rheumatism to other forms of nervous disease ought to be alluded to because it is very

marked, especially if we take the more chronic forms of rheumatism and especially the rheumatic arthritis of the finger-joints.

The pains in the limbs of which choreic children complain are very striking at times and may perhaps be of rheumatic origin, though we cannot tabulate them definitely in that way.

One word in reference to the term *functional*. That term has been making mischief for a great many years, and the sooner we get rid of it the better. We talk of functional and organic diseases as if they were different, whereas we now know they are the same. In the light of such investigations as those of Hodge, who has demonstrated the changes in form and contents of nerve-cells in bees between morning and evening under the influence of the ordinary fatigue of the day, we must admit that the difference between functional disease and organic disease is not a radical difference and not to look on the matter in this way is to abandon the attempt to discover what the structural change in so-called functional change really is. Some of the changes in chorea are very important. One of the most interesting investigations is that of Dr. C. L. Dana, of New York, who has demonstrated widespread and well-marked alteration in the ganglion cells in various parts of the brain. I have been for some time in the habit of teaching that disorders in the nervous system may arise in two principal ways; one by impairment of nutrition of the nerve elements, and the other by the failure of the proper harmony of action between different parts of the nervous system. Fright has been spoken of as causing chorea, and it certainly causes structural diseases of the spinal cord and brain.

BY DR. T. M. ROTCH.

Possibly the Society may like to hear the conclusions which I have come to from a careful study of chorea clinically, during the past twelve years. The disease is one which, to such a great extent, may be said to occur during the middle period of childhood, that we can best study it in its purity among children.

About ten years ago I wrote a lecture on chorea for my students, and, on looking over what I then wrote, it seems to me that but little additional knowledge has since been given to us concerning the etiology and pathology of the disease. We have a certain group of nervous symptoms which we designate as a disease: chorea. In a limited number of cases autopsies have revealed pathological lesions of, perhaps, the brain or heart; but in a vast number of cases we are pretty sure that these lesions do not exist. We should, therefore, recognize that certain pathological lesions may give rise to choreiform symptoms, but that, entirely outside of these gross lesions, there may be such a disturbance of the vitality of the nervous centres, as to cause these same symptoms, which represent the disease chorea, and which alone we shall designate as chorea. The relation existing between cardiac disease and chorea is an interesting one, but we should, to fully understand it, recognize that cardiac disease in young children, especially at the time when chorea is most apt to occur, is a disease essentially of inanition, and from its producing a lack of proper blood-supply to the nerve centres, strikes directly at their vitality. Any disease of an exhausting type may produce chorea in children, where such a condition of inanition of the nervous centres would

not occur in adult life, and the great preponderance of cases of chorea in children, in comparison with adults, is very significant and valuable in eliminating gross pathological cardiac lesions, so common in adults, as a cause of the disease.

Dr. Morris Lewis's figures have also been used to prove that chorea is rather a disease of inanition, and I think the matter of dispute is that class of cases—not the class of cases of organic disease which have been known for years—but the class of cases that have not generally been explained. As the children begin to go to school they begin to have attacks of chorea, and these attacks culminate in March and April. We have cases of chorea caused by lumbricoid worms. Then it is simply a result. They are choreiform symptoms following a cause.

As to the severity of the disease, we have very severe cases brought to the Children's Hospital, and I should say as a rule, we do not lose them. When the children die it is almost always found that they have some definite organic disease causing the death, and not the chorea, and some of our worst cases have recovered and have shown no signs of organic disease from the beginning to the end of the attack.

BY DR. E. M. BUCKINGHAM.

I have tried for a number of years to investigate the true relation of the heart to chorea, and to separate the functional cases from the organic. Although I have not arranged my figures, I think they would give a comparatively small proportion of disease of the heart. I feel quite sure that one half of my cases did not have any heart symptoms whatsoever. Of those that did, by far the greater number got over all heart symptoms as they got over chorea, and I should not be willing in the case of chorea, to make the diagnosis of valvular disease of the heart unless I had a very clear case, because you get anemic cases in which there is a systolic murmur, the second pulmonic accentuated, the circulation poor, and they get entirely over every symptom. I question if you may not have a valve occasionally and temporarily forced by the violent irregular motions in a weak heart. The matter of fright, also, needs to be analyzed fully as carefully as disease of the heart. It is easy to get a history of fright if it is asked for, but in most cases this history does not bear investigation. Fright may, however, be a cause. I recall a case in which a child saw her grandmother fall downstairs and die from broken neck. This child came to the hospital the next day with very severe chorea, which she did not have before.

BY DR. J. A. JEFFRIES.

I have gone over my notes of seventy-three cases of chorea, all seen during the last three years. Of these, fifty-one were girls, and twenty-two boys. The ages most affected, dating from the first attack, are the ninth and twelfth years. In only four cases could I get anything like a history of rheumatism, as follows:

Girl, ten years old. Mitral systolic murmur; had much pain in elbow, but no objective symptoms.

Girl, nine years old. Heart negative; had pain, redness and swelling in knees during the onset of the chorea.

Boy, four years old. Mitral systolic murmur; had much pain in joints, no objective symptoms.

Girl, fifteen years old. Heart normal; had pain,

redness and swelling at right knee some months before the chorea.

Of course, a few others said they had had rheumatism when asked, but they were unable to say what it was like. As to heart trouble, eleven have had distinct murmurs, loudest over the apex, systolic in time, which were persistent. In many of these cases the sound was transmitted round the side and the heart and liver were enlarged. One case had a distinct murmur, loudest over the aortic valve, systolic in time. In all, twelve cases of organic heart trouble, that is, one in six. In eleven of the cases the heart trouble was found at the first visit, and in several must have antedated the chorea. In the other, the heart trouble developed after the chorea had existed for three years, the chorea itself in this case dating from recovery of consciousness after a stunning blow on the head. Besides the above I have had a few cases with transitory murmurs—in all probability functional in nature. So far there has been but one death, this from acute endocarditis. But in several instances other children of the family have died of chorea with heart trouble. Not rarely the father had had chorea, but in none of my cases the mother.

BY DR. C. W. TOWNSEND.

I am analyzing the cases of chorea and rheumatism at the out-patient department of the Boston Children's Hospital. The results from one hundred and forty-eight cases show a connection between chorea and rheumatism. I was surprised at the large number of cases of rheumatism, and was also interested to find that in some cases, put down at first as having a murmur, possibly a transitory murmur with no enlargement of the heart or any symptoms of organic disease of the heart except the existence of a murmur, undoubted organic disease of the heart has since developed.

As to the existence of fright as a cause of chorea and the coexistence at the same time of organic heart disease, there was one case at the Children's Hospital of a girl who had been under observation since 1883. She had a severe fright caused by a dog rushing at her. An attack of chorea followed. A year or two later there was another attack, but during this time there was no rheumatism, and no murmur could be heard at the heart. Several years later she came to the hospital and had a slight murmur at the heart and slight symptoms of heart disease. These have gradually increased so that the child is now very ill, if not dead, from organic disease of the heart. During the last few years she has had a third attack of chorea, but she has never had rheumatism.

INTERNATIONAL SANITARY CONFERENCE AT VENICE.—On the 5th of January next, Venice will be the seat of an international conference, the object of which is to reorganize the Sanitary Commission of Alexandria and the conditions under which vessels in quarantine may be authorized to pass through the Suez Canal. Invitations to assist at it have been issued by the Austro-Hungarian Government in concert with those of Great Britain and Italy. The Italian delegates are already known to be Count D'Arco, Under-Secretary of State to the Minister for Foreign Affairs; the Commendatore Pagliani, Director of the Sanitary Board; and Signor Carcano, Consul.

# A CASE SUGGESTING THE ADVANTAGE OF REPEATED SUPRAPUBIC ASPIRATIONS OF THE BLADDER, AS COMPARED WITH CATHETERIZATION FOR THE RELIEF OF RETENTION OF URINE DUE TO PROSTATIC HYPERTROPHY.

BY FRANCIS SEDGWICK WATSON, M.D.

In the course of the discussion following a paper upon "The Non-Operative Treatment of the Hypertrophied Prostate," read by Dr. A. T. Cabot, before this Society last winter, I quoted the experience and advice of Mr. Reginald Harrison in regard to the value of repeated aspirations of the bladder above the symphysis pubis, to relieve the overdistended organ, in certain cases of urinary retention due to prostatic hypertrophy, and referred to the small number of cases reported by Mr. Harrison (in one of which the aspirations had been very frequently repeated), in illustration of the possible benefits from this treatment.

To-night I wish to add another case, occurring in my service at the City Hospital last summer, in which the patient's condition seemed to me to be so hopeless at the time of his entrance, that I was quite unprepared for his recovery, which it seemed to me at the time, was, in some measure, at least, contributed to by even the small number of aspirations that were employed.

There is no condition in the progress of a case of prostatic hypertrophy, the treatment of which involves so much danger to the patient, or presents so embarrassing a dilemma to the surgeon, as that of relieving an overdistended bladder, which after carrying a large quantity of residual urine for many weeks or months, has finally reached the point of overflow or complete urinary retention.

The dilemma is this: If such a bladder be emptied by the catheter, even with all the precautions which should always be used, such as cleanliness of the instrument, gentleness in its passage, the selection of the best form of catheter, the gradual withdrawal of the urine by repeated catheterizations, removing but a few ounces at first at each time, and replacing a portion of the quantity of urine withdrawn at each use of the catheter with some one of the milder antiseptic fluids, keeping the patient in bed, or at least in the house, etc., still then the subsequent occurrence of "urinary fever" with frequently a fatal termination, is an experience with which we are most of us familiar.

If, on the other hand, such a bladder is not relieved, death from uræmia and exhaustion is practically inevitable within a comparatively short time. It will be of decided value, therefore, if it can be shown in a large number of cases that the gradual emptying of such bladders can be more safely accomplished by repeated aspirations or by beginning in this way, and later substituting the catheter. My trial of this method of treatment in the following case was but a partial one, and should be considered as suggestive of its possible benefits, rather than as a proof.

The patient was fifty-nine years old; had had symptoms of prostatic enlargement for two years; for five months very frequent urination; an overflow bladder for three weeks. Urine alkaline, pale, specific gravity 1005, a faint trace of albumen. The bladder was distended to within two inches of the umbilicus. Rectal examination showed a moderate bilateral hyper-

trophy of prostate. The patient was in an exceedingly feeble and prostrated condition, and looked like a man likely to die in a few days.

June 24th. Aspirations above pubes begun and continued, as follows:

	Morning.	Afternoon.	Evening.
June 24th . . . . .	ix.	xv.	xij.
June 25th . . . . .	xv.	xv.	xij.
June 26th . . . . .	xv.	xv.	xx (cath.).

June 27th. The use of the catheter was begun. Up to this time the patient had improved in every way, and the specific gravity of the urine had risen from 1005 to 1013. The catheter was used three or four times in each twenty-four hours, a larger quantity of urine being withdrawn at each time, and a small quantity of boric acid being substituted for a part of the urine withdrawn. Polyuria, that is so frequently observed to occur under these conditions, occurred as soon as the catheter was begun, and the quantity of urine withdrawn during one period of twenty-four hours, was one hundred and eighteen ounces and then the bladder was not wholly emptied at any time. The final evacuation of the bladder was not accomplished until three weeks after beginning to use the catheter.

During the three days in which the aspirations were carried out, there was no unfavorable symptom, but very marked improvement in every regard, and the rapid rise in the specific gravity of the urine, 1005 to 1013, was noteworthy. Two days after beginning the use of the catheter, the patient had a chill and rise of temperature to 104°; was delirious for a few hours but improved on the following day, and from that time progressed steadily toward recovery, leaving the hospital at the end of two months from time of entrance, with good appetite and strength, and *what is most unusual in such a case, he had regained the power of wholly emptying his bladder voluntarily*, so that there was no residual urine.

I could not help feeling at the time that this patient would probably have died had the catheter been used at the outset. There is, of course, no proof that this would have been the case, but the rapid gain and entire absence of disturbance while the aspirator was being used, and the occurrence of the chill, high temperature, and delirium, following soon upon the first use of the catheter, is suggestive. I was driven in this case to substitute the catheter for the aspirator at the end of the third day by a threatened abscess formation at the site of the punctures, else I should have persisted in its use until the bladder had finally been emptied — by gradually withdrawing larger quantities of urine at each successive aspiration.

This method of treatment seems to merit more extended trials. It is true that occasionally a moderate urinary oozing will take place through the puncture into the prevesical space — but this is not usual if a fine needle be used. The rarer accident of wounding a peritonæum that has become bound down to the tissues about the symphysis pubis by inflammatory processes, is so slightly probable that it can be disregarded. The pain caused by the punctures is ordinarily so slight that it may be disregarded. The punctures should be repeated until the bladder has been at some one aspiration, very nearly emptied, unless there is some good reason for desisting.

Of course this procedure is in no sense a new one, and has been often employed for this purpose, but it seems to be lost sight of from time to time, which is my reason for presenting this case.

## Clinical Department.

### A CASE OF AMMONIA-POISONING, WITH UNUSUAL FEATURES.<sup>1</sup>

BY PROF. J. M. DACOSTA, M.D., LL.D., OF PHILADELPHIA.

PATRICK G., a gang-boss, or foreman of a gang of laborers, white, forty-six years of age, was brought to the accident-ward of the Pennsylvania Hospital a little after midnight on the morning of November 24th, with the statement that about two hours previously, he had swallowed, by mistake, a quantity of a strong solution of ammonia, of the kind used for cleaning grease from clothing, known as "household ammonia." It was uncertain how much passed into the œsophagus, as he claimed that he took a gulp and, finding that he had made a mistake, immediately spat it out again. A physician administered vinegar, and subsequently milk in considerable quantity. He had been in excellent general health up to the time of the accident. Upon admission, his mind was clear, his skin natural, his pulse 110, regular and of good volume. He had not vomited. The respirations were labored and somewhat stertorous, 28 to the minute. His voice was muffled and husky, apparently the result of some œdema of the glottis. The lips, gums and tongue were swollen; the latter has its epithelium entirely taken off, leaving exposed a red, raw surface. Two days later, when the swelling of the tongue had subsided sufficiently to make a digital examination, it was discovered that the tonsils were very much enlarged, nearly meeting in the middle, and the uvula was elongated and œdematous. Under the treatment instituted upon admission — ice-compresses to the neck, applications of oil and demulcents to the tongue and throat, and a milk diet — he improved markedly upon the day after entering the hospital; but, on the second night, he complained of headache, and was delirious. This condition only existed for the one night, however, and these were the only nervous symptoms presented during the time he was under treatment. Soon after admission, the stertorous breathing disappeared; but it was followed by a slight cough with considerable blood-streaked expectoration, which may have come principally from his mouth where there was extensive excoriation. He also complained of pain in the left side of his chest; but physical examination failed to detect any abnormality in the lung. It should be stated, in connection with the swelling of the tonsils two days after the accident, that there was also enlargement of the lymphatic glands under the angle of the jaw on each side of the neck. His temperature was 99.5° upon admission, and the next morning it was 100.5°; subsequently it remained between 99° and 100°.

There was one feature in the case which demands special consideration. On the day after admission, it was noted that his urine was diminished in quantity, not more than twenty-six ounces in twenty-four hours. It was turbid and high colored, specific gravity 1.024, slightly alkaline in reaction and heavily albuminous, about sixty per cent., estimated by bulk of coagulum after boiling in a test-tube. The examination with the microscope revealed red-blood disks and leucocytes, also numerous epithelial, hyaline and slightly granular casts. This was coincident with the headache and delirium already mentioned.

On the 26th, it was recorded that the urine showed merely a small amount of albumen, with only a few epithelial and hyaline casts. The following day the urine was found to be entirely free from albumen; but, on the morning of the 28th, a trace was detected. For this condition of acute Bright's disease of the kidneys, he was given infusion of digitalis, commencing with a dessertspoonful dose, at first, afterwards increasing to a tablespoonful, so that he took about two ounces daily.

Under the use of glycerine and water to the tongue and diluent drinks, the mouth was restored to a healthy condition and the œdema of the uvula passed away; his voice also regained its natural tone. It was considered advisable to retain him in the ward for a few days as a matter of precaution, but he was convalescent when presented to the class.

This case affords an illustration of the effects of swallowing a strong solution of ammonia by a man, who, up to the time of this accident, was in excellent health. The first point to which I will call attention is the local effect of the strong alkali upon the mouth and throat. Swelling of the tonsils and tongue occurred almost immediately, with œdema of the uvula, and in this acute inflammation the larynx participated, so that death by suffocation, appeared imminent. After the subsidence of the acute swelling, the epithelium came off, making it difficult for the patient to take any nourishment. By the local use of glycerine and water by demulcent drinks and a strict milk diet, he was enabled to keep up until the severe symptoms subsided. With the local inflammation just mentioned, there was slight fever; but the most interesting point in connection with this case is the kidney disorder. This was characterized at first by evidence of congestion or hyperemia, which must have rapidly passed into acute tubal nephritis. The large amount of albumen at the beginning was partly due to hemorrhage from the parenchyma of the kidneys. This was followed by the free desquamation of renal epithelium, in the form of epithelial casts, associated with exudation casts, some of which were granular. Not the least interesting point was the rapid subsidence of the kidney affection under the influence of the digitalis and the milk-diet. The casts all disappeared, and of the albumen an occasional trace only remained. It is natural to ask what gave rise to the acute Bright's disease in this case. Of course, it could be suggested that it was due directly to the ammonia, which, after being swallowed, entered the blood and passed out again by the kidneys. While that might be partly true, it occurred to me that the kidney affection might be likened to that which happens in cases of burns of the skin. In such cases, as I pointed out a number of years ago, we have an acute parenchymatous nephritis developed, when the skin is burned to any considerable extent. Why should we not have a similar state of affairs resulting when the mucous membrane is extensively burned, as it was in this case with ammonia? However, whatever be the exact cause of the kidney disorder, the inflammation was most manifest; it was not simply a case of congestion, but a typical case of acute parenchymatous inflammation, as the tube-casts proved. In connection with this, we might ask, "Would the condition of the kidneys not account for the headache and the delirium?" Furthermore, might not this kidney lesion be the cause of what has been noticed in some instances of ammonia-poisoning, the convulsions? These have been thought by Lange to be due to direct stimulation

<sup>1</sup> Abstract of a Clinical Lecture, delivered at the Pennsylvania Hospital, Phila., November 28, 1891.

of the motor function of the spinal cord, but they may well be uræmic in character; the delirium and headache in this case certainly bear this interpretation.

As regards treatment of this case, in point of fact, it was the immediate administration of the vinegar and the milk, and the local application to the burnt parts, by the physician who sent him to the hospital, that was of the greatest service to the patient. There is always great risk of the rapid development of œdema of the glottis in these cases, where a powerful irritant has been swallowed, and the resident very properly prepared everything for the prompt performance of tracheotomy, which fortunately was not rendered necessary by increase of the swelling. The importance of examination of the urine, in these cases of ammonia-poisoning, was well illustrated in this case. The condition was met here by the administration of digitalis, a milk-diet and an occasional laxative. The recognition, early in the course of the case, of the disease of the kidneys, and the prompt resort to appropriate treatment, might serve to avert lesions which would perhaps be of more danger than the primary effects of the ammonia, in the mouth, throat and surrounding parts.

The urine, in this case was found to be slightly alkaline, which was probably due to the presence of blood in the urine, or to the increased alkalinity of the blood from the absorption of the ammonia. It has been stated that, in some cases of ammonia-poisoning, the urine has been found to be acid; and this has been attributed to oxidation, by which the ammonia is converted in the blood into nitric acid. We have no evidence here that any such change took place.

In conclusion, I will remark that it is always of importance in cases of ammonia-poisoning which may be attended by acute inflammation of the kidneys, to keep the urine well-diluted, by the administration of such bland liquids as the patient can swallow. The question of the amount of influence which the perturbation of the nervous system, incident upon the fright and the shock had in the production of the disease of the kidneys, we cannot at present solve. The nervous system certainly governs the functions of the kidneys, and undoubtedly congestion of these organs might have such a cause as has just been suggested, yet we are scarcely prepared to assume that the inflammation may be attributed to a nervous cause alone.

#### RECOVERY IN A DESPERATE CASE OF ACONITE POISONING.

BY G. H. FITTLE, M.D., EAST CAMBRIDGE, MASS.

Two cases of aconite poisoning have occurred in Cambridge during one week recently. The first resulted fatally, the second recovered. In the first case five and one-half drachms of the tincture were ingested, in the second, seven and one-half drachms. Medical assistance was obtained within ten minutes in the first case, and not until forty-five minutes had elapsed in the second. The treatment used in the first instance I am unable to state, but of the second case I can speak as an eye-witness.

The victim of the second poisoning was a large and strong person of decidedly alcoholic habits; and at the time of the accident he was on the verge of *mania a potu*. The man had been in the habit of taking

bromide at such times and in this case he confused it with the aconite. The quantity of the official tincture taken was within ten drops of an ounce. The man, at the time, had been drinking, but his condition was not noticeable. The aconite was taken at 10.30 A. M. At 10.50 he complained of feeling sick; but no attention was paid to this on account of his known alcoholic habits. At 11.15 he first vomited, and from this time on he continued to have nausea and frequent ejections of small amounts of yellowish fluid. A little mustard water was given him by the family, but his resistance was so great that only a small amount entered his stomach and no effect was produced. At 11.30 two doctors arrived. They stayed an hour, and during that time injected three syringefuls of brandy with a little tincture of digitalis under the skin. Only once during the whole hour could the pulse be felt at the wrist. The priest was called and a fatal prognosis given to the family.

At the request of the doctor in charge of the case, I consented to stay with the man and continue the treatment of brandy and digitalis with any other additional means which should occur to me. All three doctors considered the man moribund. At this time—one hour and a half after the poisoning—the patient was lying upon his back on the floor. The face was flushed from repeated vomiting; the respiration very slow and noiseless, being barely recognizable. Muscular relaxation was great, the arms and legs, when raised, dropping helplessly. The pupils were insensible to light. The pulse at the wrist could not be detected. The arms and legs were quite cold as far as the trunk. No convulsions had occurred. The man was entirely unconscious.

I concluded that nothing but heroic measures would avail to save him. I injected as fast as possible three syringefuls of brandy, and twenty drops of digitalis under the skin. Twenty drops each of tincture of digitalis and nux vomica plus brandy and a little molasses were injected into the rectum. Mustard water was poured down the throat freely; and ether and ammonia given by the nose as fast as possible. Hot jugs and blankets were used to retain the body heat. In about twenty minutes the arms became warm as far as the elbows, and the pulse became perceptible at the wrist. Free vomiting had followed the exhibition of mustard water and this, too, seemed to rouse him somewhat. Ten drops more of digitalis and two syringefuls of brandy were now injected. The pulse strengthened somewhat, the man opened his eyes and spoke incoherently. In another half-hour he was able to roll over upon his side and vomit intelligently into a basin. Hypodermics of brandy and five-drop doses of digitalis were injected every twenty or thirty minutes. Later brandy and carbonate of ammonia were given by the mouth, not at first retained in the stomach, but finally kept down for twenty or thirty minutes.

As he recovered, he complained of his head feeling swollen and of pins and needles sticking into him everywhere, also of great numbness. In four hours' time—five and one-half hours from the time of ingestion—he seemed perfectly conscious and spoke intelligently to members of the family. About this time he complained of burning pain in the stomach and begged every minute or two for water. Mucilage of acacia with bismuth and soda was then given him and continued for several hours; also small pieces of ice and brandy by the stomach.

Seven hours after the poisoning the patient fell into a quiet sleep which lasted most of the night. Strict orders were given not to raise him from the recumbent position. Next morning he woke up weak and oblivious of almost everything which had passed on the previous day. Wherever an injection had been made sloughs came away. The sloughs, however, were superficial, except in one place where the fluid had penetrated the subcutaneous muscular tissue of the forearm which was much inflamed at the time of writing.

Three days after the poisoning, the patient, though still weak, was able to be about and to do light work.

## Medical Progress.

### RECENT PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D.

#### THE TREATMENT OF SPASMODIC TORTICOLLIS BY RESECTION OF THE SPINAL NERVE.

In an exhaustive article on this subject, in the *Revue d'Orthopédie*, July 1, 1891, the writer cites the following result of cases which he had collected: Out of 24 cases there were 11 with cure; there was considerable improvement in seven; there was slight improvement in two; a temporary improvement in three; one death from flagrant erysipelas. The conclusions which he draws are as follows: that in spasmodic torticollis, where all other methods have failed, the resection of the spinal nerve is justifiable. This operation is easy to do, is not dangerous, and can in a majority of cases produce excellent results (that is, in 18 out of 24). The procedure which is the preferable one is that which consists in making an incision along the anterior border of the sterno-mastoid, starting from the summit of the mastoid process. The cure is rarely immediate, but there remain for some time spasmodic movements produced, not by the contraction of the sternal mastoid and the trapezius, which are paralyzed, but by the other muscles. These secondary movements diminish gradually and finally disappear, either in whole or in part; in a small number of cases they persist. If the movements persist, one can have recourse to resection of the branch of the fascia or of the posterior branch of the cervical nerve, after the procedure of Keen. After the operation it is necessary, to complete the cure, to employ massage for the muscles already contracted, or the wearing of an apparatus, which should be worn several months or longer.

#### ON THE OPERATION AND PATHOLOGY FOR CONGENITAL WRY-NECK.<sup>1</sup>

The author's investigations are based upon three cases of congenital wry-neck operated on by open incision by Volkmann in 1880. During the operation he was able to demonstrate a point of fibrous degeneration of the muscles. A little portion of the muscle at the point where degeneration existed was excised, and histologically one could demonstrate that the muscular fascia were diminished in number and atrophied. The name of muscular callosities, or fibrous myositis, described the condition. The author mentions that the section by open incision was already done by Roonhuysen in 1670. The subcutaneous section has

the advantage in cosmetic results; open incision has the advantage of greater thoroughness. Volkmann made the incision a longitudinal one; and in this way the degenerated muscle can be removed, which the author thinks is less readily done by transverse incision.

The following directions are advised by Keen, of Philadelphia, for the division of the cervical nerves:

A transverse incision is made half-way below the tip of the lobule of the ear, extending from the median line of the neck backwards, or even forcing slightly the median line. This incision should be two and a half to three inches long. The trapezius should be divided transversely, and the occipital nerve can be found as it diverges from the complexus and enters the trapezius. The nerve emerges from the complexus at a point situated in this aponeurosis and the median line, ordinarily half an inch above the incision — sometimes higher — and then enters into the trapezius, and can easily be found. The complexus muscle should be divided transversely at the level of the nerve, and the second cervical nerve if found. The inferior oblique muscles can be recognized, following the sub-occipital nerve towards the spinal column. The sub-occipital triangle can be recognized, formed by the two oblique muscles and the large posterior muscle of the neck. In this triangle the sub-occipital is found. The nerve should always be tied with a large catgut.

#### CONGENITAL WRY-NECK.<sup>2</sup>

The writer believes that Stromeyer's explanation of the origin of congenital wry-neck is a faulty one. As is well known, Stromeyer believed that the deformity was caused by a rupture of the sterno-cleido-mastoid at birth. Petersen thinks that there is no clinical or pathological proof to justify this belief; and he has endeavored to sustain his views by experiments upon animals. He thinks that the deformity is due entirely to uterine pressure, and that the nurse or attending physician is in no way responsible for the existence of the deformity. The view of Stromeyer is supported by Colombara, and by Maas, as well as by Billroth, but the writer claims that they have not sufficient proof to justify such an opinion. He claims that there is no single recorded case of a rupture of the sterno-cleido-mastoid in medical literature causing the deformity.

#### SYPHILITIC DISEASE OF JOINTS.<sup>3</sup>

Mr. Anthony Bowley reports six cases in which the joints became affected in syphilitic patients, and in whom the joint affection was probably specific. In one fatal case, gummata was found (two on the synovial membrane), while the lower part of the femur was roughened, and the periosteum thickened and loose. Five of the cases yielded quickly to the specific treatment; the sixth died. One of the cases presented a synovitis resembling rheumatic or traumatic; two were periostitis of the articular ends of the long bones; two were examples of gummata of the synovial membrane; and in one the joint was involved secondarily to a gumma in the muscles, and resulted from the extension of the primary lesion.

#### STATISTICS OF DEFORMITY.<sup>4</sup>

The writer has collected the following statistics: Out of 67,919 patients, 1,444 were afflicted with some

<sup>1</sup> Villert: *Centralblatt für Chirurgie*, September 29, 1890, No. 38.

<sup>2</sup> Petersen: *Zeitschrift für Orthopädische Chirurgie*, 1, 1, p. 112.  
<sup>3</sup> St. Bartholomew's Hospital Reports, 1890, vol. XXV, p. 83.  
<sup>4</sup> Hoffa: *Münchener Medizinische Wochenschrift*, 1890, No. 23.

form of deformity, that it is to say, two cases of deformity to 100 surgical patients. The numbers of men and women were equal. The ten first years of life furnished the larger contingent of deformities, and this number diminishes rapidly with increase of age. Congenital deformities are eight times less frequent than the acquired deformities. Of the latter (1,175 in all), 226 were rickety, 89 paralytic, 142 tuberculous, and 944 static. In regard to the seat of the deformity, it was equally frequent on the right as on the left side; twice as often bilaterally as unilaterally. The inferior extremities and the trunk were affected, rarely the neck and the upper extremities.

#### MYOSITIS OSSIFICANS.\*

A case of this disease is reported occurring in a child of four, otherwise well and of good family history. From the age of two, at intervals, "lumps" appeared on different parts of the body, which disappeared spontaneously. At the time of observation, there was restriction in the motions of the head, shoulder and elbow, due to a semi-ossified condition of the muscles. There were several nodes scattered over the head and back, and the tendons of the teres major and the latissimus dorsi, and the sterno-mastoid muscles were the seat of the most pronounced change. For the last two years, the child had been subjected to general constitutional treatment, and to the iodide, mercury, arsenic and phosphorus, but without apparent benefit. The node in the left axilla was cut down upon, and the teres major was found to be a complete mass of bone, with a fibrous attachment at either end; and other muscles were in a similar condition.

#### OSTEOMYELITIS DEFORMANS.†

In an article on this subject, Dr. E. Vincent gives in detail a case in many respects unique, and reviews the forms of osteomyelitis in a thorough way. The case is of a girl of thirteen, with a uniform enlargement of the left tibia, presenting a pronounced antero-posterior curve, and with a resulting genu valgum. The enlargement was, in general, smooth, affecting the length as well as the volume, and had existed about four years. There had been but little pain or interference with the use of the limb, and the general health had not suffered, except that there was distinct anæmia. By a longitudinal osteotomy, a section of the bone was removed, and in structure this was found to be everywhere dense and resistant, with no sign of abscess, sequestrum, cavity or focus of inflammation, but the medullary canal had entirely disappeared, having been replaced by a process of ossification. Eighteen months later there was shown a diminution in the volume of the bone, but the same difference in the length. The walk had improved. The patient gave no evidence of specific taint other than that of a double iritis at the age of twelve.

The different forms of osteomyelitis are carefully and thoroughly considered, but all are excluded except that of a diffuse syphilitic, the result of a late manifestation of this taint, acquired at an early age or else congenital. In many ways it does not correspond to the recognised forms of this disease, as it was confined to one bone, and in the absence of severe nocturnal pains, of exostosis, of foci of the disease, or of cavities

of old processes. The author suggests, however, that had he pursued the examination to a greater extent, some evidence of this might have been found. He inclined to regard it as a late manifestation of syphilis, appearing in a manner rather unique, and suggests the term of "*a'ostéo-syphilome pandia physaire hypertrophiant*."

#### DEFORMITY OF THORAX DUE TO NASAL OBSTRUCTION.

Rédard, in the *Gazette Médicale*, Paris, (March 22, 1890, p. 124), gives the result of his investigations, with the following conclusions: (1) Nasal obstruction is the frequent cause of kyphosis, scoliosis and thoracic deformities. The scoliosis is generally dorsal, with a long curve and not pronounced. The thoracic deformities noticed are due to nasal obstruction due to adenoids rather than to enlargement of the tonsils. The treatment of nasal obstruction improves certain forms of deformities of the thorax quite rapidly, and special gymnastic exercises are not to be advised until the affection of the pharynx or nose is cured.

The same subject is investigated by Phocas in an article in the *Revue d'Orthopédie*, in May, 1890.

An explanation of this deformity is given differently by different writers; some refer it to the atmospheric pressure, others to the action of the diaphragm. The chief cause, however, is the narrowing of the nasopharyngeal canal, and the flexibility and the weakness of the arch of the ribs in a child accomplish the rest. The simple narrowing of the canal by enlargement of the tonsils is in a majority of cases not sufficient to produce the deformity; adenoid hypertrophy added to this, combined with a lack of resistance in the thoracic bones, brings about the distortion.

#### DISSECTION OF THE CONGENITAL CLUB-FOOT.‡

A careful dissection of the foot is given, with illustration, showing the alterations in the shape of the bone. There is also an excellent article by Sauton in the same magazine on the same subject, and they both illustrate the osseous alterations which are to be seen in this deformity. The conclusions which the latter writer draws are, that the causes of the deformity, and therefore the obstacles to reduction, are many, and are seated, both in the skin and in the soft parts, as well as in the relation of the bones to each other. If the muscles and ligaments were the only things, the treatment would be comparatively easy, but unfortunately there are osseous obstacles, due to the change of shape of the bones.

#### TIBIO-TARSAL RESECTION BY THE REMOVAL OF THE ASTRAGALUS.§

The writer, who is the chief assistant of Ollier, recommends the removal of the astragalus in cases of tubercular disease of the ankle as a method of treatment, and as preliminary to the ordinary resection. The advantage that he claims for the method is that it gives much greater room for inspection of the diseased part than the usual method of resection. The results are excellent. It should be remembered that the removal of the astragalus leaves a cavity in which pathological fluid may collect, and that this should be drained, and that there should, therefore, be counter-openings on each side of the tendo Achillis. Ollier uses two anterior incisions for the removal of the astragalus.

\* M. R. Gordon Macdonald. *British Medical Journal*, 1891, Aug. 22, p. 427.  
† *Revue d'Orthopédie*, 1891, vol vi, p. 101.

‡ *Revue d'Orthopédie*, September 1, 1891.  
§ *Bulletin de Chirurgie*, August, 1890.

# PHELPS'S OPERATION FOR THE TREATMENT OF EQUINO-VARUS.<sup>9</sup>

The writer collects thirteen cases treated by Phelps's method with good results; and statistics by Schreiber show eleven cases treated by this method with success. The operation of Phelps was done by him on two children three years of age, one thirteen months and another eight years. He draws the following conclusions: that the orthopedic result obtained by Phelps's method is excellent, and generally superior to that which follows extirpation of the astragalus. The operation is applicable not only to children, but also to adults. The dissection treatment is of great importance.

## FORCIBLE CORRECTION OF CLUB-FOOT.<sup>10</sup>

König is an advocate in all cases of club-foot, of subcutaneous tenotomy of the tendo Achillis and of the plantar fascia before forcible correction. The patient then is placed on a table, turned on the side, and knees well fixed; the convex portion of the foot rests upon a triangular piece of wood. The operator seizes the foot in such a way that he can let his weight fall upon the front of the foot by means of one hand, holding the back of the foot with the other; the wooden block acting as the fulcrum of resistance, the astragalus resting upon this. In this way great force can be used, and the ligaments can be stretched or torn. The patient is then turned upon the back, and forcible flexion is used, the leg being held by the hand of an assistant. Sometimes one sitting is enough, but often two or three or even four are necessary. Between these the foot is held in position by bandages. When the patient is able to go about, apparatus is used. The second sitting is required, as a rule, in about fourteen days. The rupture of the skin in the hollow of the foot is sometimes met, but the wound is stitched with catgut, and heals under the dressing.

## TREATMENT OF CLUBFOOT BY OSTEOCLASIS OF TIBIA AND FIBULA.

Grattan, in the *British Medical Journal* (May 2, 1891), advises the treatment of the most severe forms of club-foot by osteoclasis of the tibia and of the fibula in addition to the operations on the tarsus. He removes the astragalus first, but afterwards he recommends the fracture of fibula and tibia at the junction of the middle and lower third. At the end of ten days after the fracture, the splint which holds the limb in position can be removed. The subsequent treatment is of great importance to prevent the foot from turning in its old position. The patient need not wear shoes, but should walk barefooted.

## OPERATION TREATMENT OF CALCANEI.<sup>11</sup>

There are two operative methods; one recommended by Allandale, Willett, Walsham, Gibney and Kirmisson. It consists of shortening the tendo Achillis. The second by Nicoladoni and Hacker consists of transplantation of the peroneus fascia into the tendo Achillis. Both of these operations have value. As to which is preferable, the writer prefers the shortening of the tendo Achillis, if the gastrocnemius and soleus are healthy; that is, if they react to electrical irritation, the slightest irritation being of value, and found in a majority of cases. The plantar fascia is of importance, as it may be contracted. In only a certain number is

the method not of use, and those are where there is deformity of the os calcis.

## LINEAR OSTECTOMY OF THE TIBIA AND THE FIBULA IN PAINFUL FLAT-FOOT.

Kummer describes this method of operation in a case of flat foot following fracture. He adopted the method of osteotomy advocated by Kredelesburg, in *Archives of Chemical Surgery*. (Vol. XXXIX, 1889, p. 751). The incision is three centimetres long made on the crest of the tibia, three centimetres above the tibio-tarsal articulation. The periosteum is detached from the limb, lifted, and by means of a needle the chain saw is passed round the tibia, and the same thing is done by the fibula. The foot is immediately put in position, and the pronation changed to a slight supination. The result reported is excellent; as are the results mentioned by Kredelesburg.

## CONGENITAL FORWARD LUXATION OF THE TIBIA.

Pochas<sup>12</sup> has collected twenty-three cases of this rare affection, which was first described by Chatelein and Malgaigne, and has been mentioned by several French writers. In eighteen the deformity occurred in children otherwise well-formed; in five where there was some malformation. The characteristic was hyper-extension of the leg from the thigh; in other words, a bending of the knee in a reverse direction, as if the extensors of the thigh had become flexors. In thirteen of the patients the anterior face of the leg was in contact with the anterior face of the thigh. The obstacles to correction are: (1) muscular, due to the contraction of the anterior portions of the thigh; and (2) osseous, from the projection of the femoral condyles. The muscular resistance can be overcome; the osseous is insurmountable, unless the limb is reduced. In certain cases reduction can be easily made by means of manipulations. In other cases reduction has been unsuccessful, although the limb can be made nearly straight, but complete correction has not been possible. Weinlechner considers a complete cure as very rare, on account of the condition of the ligaments; while others take a more favorable view of the case. Treatment consists in reducing the deformity, and then retaining the reduction. In certain cases the reduction is easy, but the retention of the reduction is difficult; in other cases reduction cannot be obtained; in the majority of cases, simple means, such as plaster-of-Paris or paste-board splints are sufficient to retain the limb in the corrected position. In a few cases simple treatment is insufficient. In these it is better to attempt reduction even at the risk of an operative interference. Such operation consists of a manual osteoclasis above the condyles.

## GENU RECURVATURE ON BOTH SIDES.<sup>13</sup>

Mr. Edmund Owen describes a congenital case of this condition, in which the dorsum of each foot usually rested on the clavicle, with the knees bent sharply backward. The backward displacement of the tibia was such that the inter-condylar notch could be clearly defined in the popliteal space, and there was a transverse furrow at the front of the knee. Flexion in the proper direction was impossible, even under chloroform. Mr. Owen operated by section of the quadriceps tendon through an open transverse incision, which exposed the trochlear surface. Two months afterwards, the

<sup>12</sup> *Review of Orthopedic*, January 1, 1891, p. 36.

<sup>13</sup> *Medical Society Transactions*, vol. XIV.

knees could be flexed to 90°, and the child was beginning to acquire some power over them.

#### CONTRIBUTION TO THE OPERATIVE TREATMENT OF THE DEFORMITIES OF THE LOWER EXTREMITIES.<sup>14</sup>

The number of operations performed by this surgeon is 170. The osteotomies are 120. Among these osteotomies, 16 were by the method of MacEwen; 28 were subcutaneous, and 48 open. Six were made on the femur, 14 on the tibia (by Billroth's method), 22 on the shaft of the tibia, and two wedge-shaped resections of the periosteum. Motta uses continuous extension by weight, following osteotomy, in 57 cases; and he does not use manual correction. The corrective action of weight shows itself in three or four days. Many of the osteotomies were done with open incision. The results were excellent. As a rule, there was no reaction. In 120 osteotomies there were four with suppuration, and in two of these cases there was a sequestrum; in five cases gangrene of the limb, and amputation. The osteotomy was done according to the method of Billroth, and the knee contained pus. The patients recovered. The callus is ordinarily solid in thirty-five days. Motta has also done 17 osteoclases, and 53 forcible corrections. He does not advise the use of appliances after the operation.

#### OSTEOCLASIS.<sup>15</sup>

Boy, fifteen years of age, always well, presented himself with a history of limp in his gait for the last two years. He was easily fatigued while walking. Never any swelling or pain in the hips. He was never obliged to stay in bed. The thighs were in a position of forced adduction. The upper part of the body leaned forward while walking; the inferior lower extremities were shortened to the extent of a centimetre; the top of the great trochanter was three centimetres to the right; the left two centimetres above the Nelaton line. As there was no question of coxalgia or of congenital dislocation of the hip or of fracture, the case must necessarily be one of curvature of the neck of the femur, more marked on the right than on the left, and due to delayed rickets. Massage wrought some improvement in the symptoms. The author refers to the articles of Muller and Lanenstein. Readers will recall the case reported by Dr. Monks, of this city, in the *Boston Medical and Surgical Journal*.

#### ARTHRODESIS.<sup>16</sup>

Case of infantile paralysis of the left leg in a child of fifteen years. The child could neither walk nor stand upright. December, 1889, the operation for arthrodesis of the knee was performed, with suture of the bone. There was fixation of the patella, and there was a complete union. Two months afterward arthrodesis in the tibio-tarsal and medio-tarsal ligament was performed. Winthwarter found that the osseous union was obtained with more difficulty in the tibio-tarsal articulation, which in this case was fixed in part by a fibrous mass. The result was excellent, and the patient was able to walk with a cane, and could stand without any support for a portion of the day and could work as a laborer.

Arthrodesis was first introduced by Albert, in 1878; since that time it has been often done, especially, in Germany. It has been little attempted in France,

though Kirrmisson has attempted it in some cases. It is analogous to a resection, but differs in the fact that in resection one ordinarily hopes to obtain success with some motion; in arthrodesis, on the contrary, one attempts to avoid movement.

The technique of the operation is most simple. One opens the joint with the same incisions which are used for resection, and divides the soft parts, avoiding the vessels, the nerves and the tendons, if possible, though this is of less importance than in resection. As soon as the bones are reached, the ligaments are pushed aside in such a way as to lay bare the articulation, and have all the articular surface apparent. The cartilage covering the bone is then laid bare, either by means of a little knife or by means of a gouge. These abrasions should be complete, and they should penetrate as far into the innermost corners of the joint — should be sufficiently deep — reaching as far as the osseous portion; but, as far as possible, it should be desirable to avoid causing much blood between bone. The application of the different ends should be as exact as possible. The suture of the fragment is not essential, but it may be necessary, and should be done by silver wire. Some surgeons, however, use catgut. After operation the limb should be immobilized by a plaster.

(To be continued.)

## Reports of Societies.

### BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

G. G. SEARS, M.D., SECRETARY.

REGULAR Meeting, Monday, October 26, 1891, the President, DR. FREDERICK I. KNIGHT, in the chair.

DR. A. T. CABOT reported a case of

#### INTERNAL STRANGULATION.

The patient was a child of five, and had been seized suddenly with pain in the abdomen three days before he was brought to the hospital. This pain continued with more or less severity from the time of seizure. The bowels were obstinately constipated, and resisted all efforts to produce movement by injection.

At the time the child was seen he had become drowsy, and had a very quick and feeble pulse. The face was somewhat cyanosed, although the extremities were warm. The bowels were moderately distended, and while there was no excessive sensitiveness, palpation caused some pain in the lower part of the abdomen. No tumor could be felt, although there was somewhat more resistance in the right hypogastrium.

A full injection of water was given the child in an inverted position, in the effort to overcome an invagination should such exist. This was, however, of no avail, the water returning exactly as injected. It being evident that some obstructive lesion existed in the abdomen, a laparotomy was decided upon.

The abdomen was opened in the median line midway between the pubes and the umbilicus. A gangrenous coil of intestine immediately appeared in the wound. Following this down, it was found caught under a little band about a line in diameter. This band was quickly divided with scissors, and the bowel released. The gangrenous portion of bowel was rapidly removed, bleeding points in the mesentery being caught and tied, and the two extremities of the bowel were brought up

<sup>14</sup> Motta. *Archiv. f. Orthopädie*, 1891.

<sup>15</sup> Ricketts. *Minch. Medical and Surgical Journal*, 1891, No. 32.

<sup>16</sup> Winthwarter. *Revue d'Orthopédie*, March 1, 1891, p. 150.

and secured close together in the lower angle of the wound, so that if the child survived the operation, it should be possible later to restore the continuity of the bowel by a plastic operation. The operation was done with the greatest possible speed, the child's condition not admitting of delay. Although he came out of his ether well and recovered his intelligence, he lived but a few hours.

This operation was of especial interest on account of the extreme facility with which it was done. Had the case been seen while the child's strength still held out, and before the bowel became gangrenous, there was no reason why he should not have made an easy and rapid recovery.

This shows the importance of submitting cases of acute intestinal obstruction to the surgeon's knife as quickly as possible after the diagnosis is made.

The band under which this strangulation occurred, tense and fibrous in character, ran from the side of the lumen of the bowel to a point on the mesentery about three-fourths of an inch from the mesenteric attachment to the bowel. It was one of the bands so ably described by Dr. Fitz in his paper on "Omphalo-Mesenteric Remains."

Dr. Cabot showed the piece of bowel removed, which was a portion of the ileum about ten to twelve inches in length.

DR. FARLOW showed

#### A VERY LARGE NASAL POLYP

with a long pedicle, which he had removed from the post-nasal space, the pedicle having been attached to the upper and posterior part of the right nostril.

Dr. F. S. Watson reported

#### A CASE SUGGESTING THE ADVANTAGE OF REPEATED ASPIRATIONS OF THE BLADDER, ETC.<sup>1</sup>

DR. W. C. FIELD: Listening to the remarks of Dr. Watson, I have been strongly impressed with the fact that history strangely repeats itself from one generation to the other. The plan of suprapubic puncture by means of trocar, and the introduction of the catheter through the canula, certainly was known and practised some as long ago as I was in Paris in 1852. It was somewhat in favor in different parts of Europe. I remember that Mr. Abraham Colles, in his "Surgery" (page 245), speaks of a man in his time who had puncture of the bladder above the pubis, and being an odd-tempered man he allowed the canula to remain and stopped it up with a plug of wood which he pulled out to empty the bladder from time to time as long as he lived. Somehow that fell into desuetude. I never saw it done but once and then with very evil result. That was, however, in the days before antiseptics were known or practised.

In regard to aspiration of the bladder, which my friend Reginald Harrison has written very well about: that I saw practised at the City Hospital somewhere in 1874 to 1876. There were repeated aspirations made there, but with the result that a man died, and I opened his bladder. There were little deposits of pus at the sites of punctures by the needle, and in one place quite a collection of pus. The outcome of that was not encouraging, and I am afraid if it came into general use the results might not be the best.

Puncture of the bladder, which was perhaps applicable more to cases of stricture than to enlargement of

the prostate, was the puncture of Mr. Cock's through the perineum with a double-bladed knife. That, perhaps, in the hands of Mr. Cock was a very good operation. I saw him do it. I also saw a case at the City Hospital, where a gentleman did it with an amputating knife; but the autopsy showed that the knife penetrated the bladder (both coats), and went into the cavity of the peritoneum, although he was a distinguished operator.

Now we come to Dr. Davis, of Birmingham, Alabama, who, I think, has revived the operation of suprapubic puncture. He reaches the conclusion that there is no particular necessity of making a display about it, simply push the knife into the bladder, follow that with a catheter or large drainage-tube. He has also invented what he calls an epicyclic fistula plug made of rubber or silver, which is retained and can be taken out and empty the bladder as he chooses. See pamphlet entitled "Epicyclic Surgical Fistula." One of the very best papers ever written.

In regard to suprapubic aspirations opening the bladder, it is not always applicable in all cases of disease of the prostate, because in some diseases of the prostate that you have, one comes at last on a contracted bladder which will not hold more than a half-tumblerful before it is necessary to evacuate it. In one case of prostatic disease I now have under my care, for some reason a stricture, I think, has formed somewhere in front of the prostate, and a while ago I was called to relieve him of retention, and I think I tried every sort of small catheter that the world's market affords, and nothing would enter except an olivary pointed catheter bougie, made by Vergne, of Paris. I was enabled to relieve the man in that way. I can think of no operation more applicable in that case than that of Mr. Wheelhouse, since practised by Dr. Watson and self, and modified by Dr. Watson, who retained the small catheter as a guide — a most excellent improvement — passing the staff above it, then cutting on the staff.

I think of all the plans I have seen for the treatment of retention of urine with enlarged prostate, that, if the bladder has risen high enough above the pubis, this operation by Dr. Davis, of Birmingham,<sup>2</sup> will come into play more than any other. This, original with Dr. Watson, is a distinct advance over anything yet put forward in external urethrotomy in prostatic disease, by any author or operator in the world.

Dr. A. T. CABOT said that although antiseptic precautions made operative procedure much less dangerous than it formerly was, still, he preferred careful, repeated catheterization for the gradual emptying of an enlarged bladder rather than the suprapubic puncture, either with an aspirating needle or with a trocar, followed by the introduction of a small tube.

He mentioned one case which he had many years ago, of an enlarged prostate through which a catheter could not be passed without ether, and in which repeated punctures over the pubes were carried out for a week. At the end of this time, leeches to the perineum and the administration of ergot finally succeeded in restoring the calibre to the urethra, and enabling the patient to resume micturition by the natural efforts. The prostate in this case almost filled the pelvis, and the difficulty, owing to the length of the canal, which

<sup>1</sup> This paper was read by title in the Section of Surgery and Anatomy, American Medical Association, June, 1882, by John B. S. Davis, Birmingham, Ala.

<sup>2</sup> See page 676 of the Journal.

was tortuous and at the same time very stiff, owing to the length of the fibrous tissues around it, did not allow of a manipulation of the instruments past the obstructing projections.

He recalled, in order to complete the consideration of the subject, the procedure spoken of by Mr. Harrison, of plunging the trocar directly through the perineum, through the prostate and into the bladder, leaving the canula in place for perineal drainage. Mr. Harrison used this in one case in which a very great shrinkage of the prostate afterwards occurred, and in which the proceeding was followed by great relief to the patient.

DR. CABOT said he would like to ask Dr. Watson if in his case the retention was chronic, or possibly rather acute. The recovery of the bladder after emptying rather suggests that it was a case of acute rather than an old chronic retention.

DR. FIFIELD: I think Mr. Harrison has abandoned his operation of puncturing through the perineum by means of a trocar and canula, and has substituted for that what he calls an incision on the floor of the prostate.

DR. RICHARDSON: I think aspiration of the bladder nowadays is a very safe operation indeed. Suprapubic aspirations in case of prostatic enlargement or old stricture, as compared with rectal puncture, is, I think, absolutely safe. In rectal puncture I think we have one of the most dangerous operations, owing to the fact, which is not realized, that the peritoneum often comes down so far that you would wound it. There is much more danger of wounding it by that operation than by the suprapubic. At the Carney Hospital, some ten years ago, I remember a man in whom we repeatedly punctured the bladder, with the curious fact that it enabled one to pass an instrument after a day or two. It seems to me a very rational procedure, and one in which there is but little or no danger.

DR. WATSON: In answer to Dr. Cabot's question, the case was one of undoubted chronic retention. That is the reason I mentioned the recovery of power of urination. We knew he had had overflow of the bladder for three weeks at any rate; and for three weeks after he came to the hospital nothing was done.

The suprapubic puncture is a very old procedure. As to its mortality, I had the same feeling about it as Dr. Cabot expresses. Out of ninety cases fifty died, in which Dittel made the puncture, for example; but those were not aspirations but punctures with retained canula. At the autopsies, death was seen to be frequently due to pyæmic infiltration of urine, and often phlegmon and peritonitis. There is nothing novel in the idea of aspiration of the bladder, of course; but the idea of systematically carrying it out, and repeating it frequently, with the definite intention of slowly emptying the bladder previous to using the catheter is, so far as I know, but seldom practised, and it seems to me worth while to give it a more extended trial. The power of the bladder to empty itself after this is, as Dr. Richardson remarks, a very striking fact.

THE EASTERN OPIUM TRADE.—A Chinaman named Cheng Hong Chang has gone to London to try to influence public opinion on the evils of the opium trade. He is said to be well educated and to speak English fluently.

## Recent Literature.

*A Manual and Atlas of Medical Ophthalmoscopy.* By W. R. GOWERS, M.D., F.R.S., etc. Third edition, revised throughout, with numerous additions and additional illustrations. Edited with the assistance of MARCUS GUNN, M.D., F.R.C.S., etc. One volume, pp. 330. Philadelphia: P. Blakiston, Son & Co. 1890.

The new edition of this best-known work of its class is very welcome, not only showing the appreciation of the medical world of the untiring labors and accuracy of observation of its distinguished author, but also because the book has been so made over as to be an exposition of its author's later and wider experience. The cases that were described in full in previous editions have served their purpose and brief epitomes have therefore been substituted. The methods of scientific observation and recording of cases with the ophthalmoscope are laid down with care. It is a book that every practitioner of medicine who can use the ophthalmoscope should have at hand.

*Diseases of the Eye.* By EDWARD NETTLESHIP, F.R.C.S., Ophthalmic Surgeon to St. Thomas Hospital, etc. Fourth American, from the fifth English edition. With a chapter on the examination for color-blindness by WM. THOMPSON, M.D., Professor of Ophthalmology in the Jefferson Medical College. One volume, pp. 508. Philadelphia: Lea Brothers & Co. 1890.

This little manual for students has been reviewed in these columns three times before, and, therefore, there is no need for extended comment; the book still has the faults pointed out in previous reviews. It is a most excellent little hand-book, for the purpose for which, we presume, it was intended, namely, to enable the student to pass his examination.

*Indigestion: A Manual of the Diagnosis and Modern Treatment of the Different Varieties of Dyspepsia.* By GEORGE HERSCHEL, M.D., London. London: Baillière, Tindall & Cox. 1892.

The author has undertaken to present in a form sufficiently concise and methodical to meet the requirements of students and practitioners of medicine, a *résumé* of the more important points in the diagnosis and treatment of indigestion. He has availed himself of recent information scattered through medical journals and isolated monographs.

He has attained his object in a handy and practical duodecimo of 180 pages, to which a good index and a quite full bibliography add value.

*The Physician's Visiting List* (Lindsay and Blakiston's) for 1892. Philadelphia: P. Blakiston, Son & Co.

This popular visiting list is so well known that it is unnecessary to describe it in detail. As usual it appears in four sizes, the smallest for twenty-five, the largest for one hundred patients a week; it may also be had in two volumes, one for each half year. A good dose table, and other tables needed by a physician, are condensed into thirty pages, adding to the convenience of the book, but not making it at all unwieldy in size to carry in the pocket. Besides the blank pages for the daily record of visits, are pages for memoranda, addresses, cash account, and the like.

THE BOSTON

**Medical and Surgical Journal.**

THURSDAY, DECEMBER 24, 1891.

*A Journal of Medicine, Surgery, and Allied Sciences, published at Boston, weekly, by the undersigned.***SUBSCRIPTION TERMS:** \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.*All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.**All letters containing business communications, or referring to the publication, subscription, or advertising department of this Journal, should be addressed to the undersigned.**Remittances should be made by money-order, draft or registered letter, payable to*DAMRELL & UPHAM,  
283 WASHINGTON STREET, BOSTON, MASS.**AMÆBIC DYSENTERY.**

It has been known for some time to those aware of the work being done at the Johns Hopkins Hospital, that Drs. Councilman and Lafleur were deeply busied in the prolonged and comprehensive investigation of a large number of cases of dysentery, in which the amœba coli, or, as they prefer it, amœba dysenteriae, had been found.

Despite the considerable periodical literature of this subject, the text-books give little or no information, and the physician seeks in vain for a satisfactory statement of the symptomatology and pathological anatomy of that variety of dysentery connected with the presence of amœba coli. How important their recognition may become in prevention, prognosis and treatment, is fully and clearly set forth in the work now under consideration.

The authors maintain that amœbic dysentery is a distinct disease, caused by amœba which enter the body, and produce characteristic lesions of the intestine. They may also produce abscesses of the liver, with or without lesions of the lung. Such abscesses differ in their characteristics from those occurring in other forms of dysentery. Amœbic dysentery thus differs etiologically, anatomically and clinically from other varieties of dysentery.

These claims are based upon the study of fifteen cases, twelve of which were endemic, observed between February, 1890, and September, 1891.

Dr. Lafleur, to whom we are indebted for the clinical part of the paper, found the onset of this disease to be variable, its course irregular, with frequent exacerbations and intermissions, but tending towards chronicity. Tenesmus was infrequent. The stools contained a bloody mucus but differed in physical characteristics from those seen in other kinds of dysentery. In chronic cases with a fairly good appetite and digestion, a grave anemia might exist, without the escape of blood from the rectum, owing to the destruction of red blood-corpuscles by the amœba. The prognosis is always uncertain; death may take

place at any period in the course of the disease, and recovery is always gradual. Abscess of the liver was a complication in four cases, hepato-pulmonary abscess in four, peritonitis in two, once with and once without, perforation.

The essential feature in the diagnosis is the detection of actively moving amœbae in the stools, sputum or aspirated contents of an hepatic abscess.

So complete a clinical picture as that elaborated by Dr. Lafleur has not been hitherto given, and Dr. Councilman deserves the credit of being the first to give a comprehensive and careful study of the lesions to be found in this disease. He may be said to have discovered where the amœbae enter the tissues, their course through the body, and the mischief they produce. His investigations and discoveries compare well with those of Ponfick and Israel in actinomycosis.

From his anatomical studies he concludes that the amœbae in food or drink reach the large intestine where they find favorable conditions for their increase. They multiply rapidly, produce a superficial necrosis, a softening of epithelium and an increased flow of mucus. They penetrate the mucous membrane, usually between the glands and pass into the submucous tissue where they produce an œdematous swelling with softening. The overlying tissue deprived of its blood-supply, dies, and the ulcerative process is thus begun. The ulcers increase by a progressive, undermining process, though their typical course and appearance may be modified by the action of associated bacteria. In certain places the amœbae pass through the muscular coat and produce changes in the intermuscular tissue like those in the submucous layer. These lesions thus correspond rather with those generally described under the term follicular dysentery than with those included under the catarrhal and diphtheritic varieties.

Dr. Councilman thinks the amœbae usually invade the liver by crossing the peritoneal cavity, although they may be found in lymphatics and in blood-vessels. He bases this view upon the absence of amœbae in the lymph-glands and the usual limitation of the abscess to the upper or lower surface of the right lobe of the liver, whereas, abscesses from portal embolism should be found in either lobe, deep-seated as well as superficial. The latter event occurred in one case where an amœbic embolism of the portal vessels may have caused the multiple, hepatic abscesses. It is also possible that the amœbae may enter the liver through the bile-ducts.

The abscess in the lung is usually found in one place, in the lower lobe of the right lung, where it is in contact with the diaphragm. It is considered to frequently arise from the direct extension of the hepatic abscess through the diaphragm, although an amœbic abscess may be present in the lung and the diaphragm be intact. Since the amœbic abscesses are limited to the intestine, liver and lung, a pulmonary abscess with an intact diaphragm would suggest the direct passage of the amœba through this septum.

The amœbæ seem to act upon the tissues differently from bacteria. Their typical effect is best seen in the liver where they appear to produce a necrosis of the tissue and a solution of the intercellular substance. The so-called abscess is thus made up of detritus not of pus-corpuscles. The association of the above-mentioned symptoms and lesions, meets with an important confirmation. The Army Medical Museum contains a number of specimens from cases of dysentery occurring during the war. An examination of these showed that those which presented the lesions characteristic of the presence of amœbæ came from patients whose symptoms corresponded with those observed by Lafleur in amœbic dysentery.

When one reads this interesting publication and sees the numerous and characteristic illustrations, one cannot but share in the enthusiasm which pervades every page of this important contribution.

Dr. Councilman's picture of the wanderings of these amœbæ is as graphic as if he were seeing them move from place to place in the body as he has watched their migrations on the hot stage. To us his anatomical facts are more convincing than the injections of Kartulis. The pure cultures of the amœbæ obtained by the latter are stated to have produced dysentery in cats, but Councilman finds every stopping-place in their journey through man from the surface of the colon to the interior of the spit-cup.

A word may be added of congratulation to the hospital on its good fortune in being able to furnish so important a contribution to medicine, and of thanks for presenting the work of its physicians in so satisfactory a manner.<sup>1</sup>

#### SHALL PHYSICIANS DISPENSE THEIR OWN MEDICINES?

In the earlier ages of civilization (a custom prevalent in many country places even to-day), the physician was pharmacist and druggist as well as doctor. He collected his herbs and made his blue mass and his infusions and his peristaltic pills.

Later on, the pharmacist was evolved, and the retail druggist by a further differentiation. The manufacturing pharmacist has become a necessity, obtaining from all parts of the world the drugs which the physician needs, and preparing them in all suitable forms for the latter's use, so that half the details of the materia medica become useless lumber to him; the retail druggist, if not so much a necessity, has been to such an extent a convenience and a help that more than once in medical societies, attempts have been made (as lately in Cincinnati), to make it obligatory on physicians always to prescribe, and never to dispense their medicines.

There are advantages in this system, and there are evils. It is an advantage to the physician to be delivered from the drudgery to which he would be sub-

jected were he obliged to be his own apothecary. At the same time, this drudgery is reduced to its minimum now that the day of compressed tablets has arrived. The prevailing system is doubtless sometimes a disadvantage to the patient, especially if his circumstances oblige him to be economical; he groans over a large apothecary bill, and perhaps asks if the next time he had not better employ a class of physicians who furnish their own drugs. It is doubtless true that the physician, were he to furnish his medicines, could be able to effect for his patient a great saving. This has been rendered quite possible and practicable by the manufacture and use of the pharmaceutical preparations known as tablet triturates, or compressed tablets. One of the arguments in favor of the tablet triturate is its cheapness. The pharmacist has an interest in selling these tablets at a very low rate, and by this means obtaining the trade of physicians rather than of druggists. The representative of the manufacturing house at stated periods visits all the physicians in a given locality with his samples, and for a few dollars paid on receipt of the goods, each medical man is furnished with quite an outfit of the drugs which he most uses in his practice, in a form very handy for administration..

There is a satisfaction, physicians say who now rely on the triturates and seldom write prescriptions, in being able to dispense at the bedside, and in a safe and convenient form and stated dose, the medicines indicated. Less medicine certainly will be used, though more visits may be made, as the physician (who has also a motive for economy) will leave, on making his morning visit, just the medicine for the day. Under the apothecary *régime*, bottles of unused medicine were likely to accumulate in the sick chamber, as "indications" changed.

Many physicians in large practice say that the tablet triturate and compressed tablet have "come to stay," and that it gives much better satisfaction to their office patients as well as the clientèle which they visit every day, to give them their medicine instead of a prescription, which latter must be subsequently compounded by the apothecary with more or less of delay entailed, and the exaction of another fee.

Another advantage attending the new method (or rather the revived primitive method) has been emphasized by a contemporary recently: the accidents of prescription writing and prescription filling are lessened. Mistakes have been too often made by the carelessness of the physician or the illegibility of the prescription, and by the carelessness and ignorance of the druggist. We are not sure, however, to what extent further experience will show the liability to accidents to have been diminished. The white tablets may very easily be mistaken for each other by doctor or patient, and it is very possible that morphia for instance, may be given or taken in this way for calomel.

Whether the increasing popularity of the tablet is destined largely to work against the interest of the

<sup>1</sup> Amœbic Dysentery. By William T. Councilman, M.D., and Henri A. Lafleur, M.D. The Johns Hopkins Hospital Reports, 1891, vol. II, Nos. 1, 2, 3, pp. 176, 181, 184.

retail druggist, whose shelves are already heavily weighted with the new preparations—some salable and some very unsalable—which he must “carry” in order to keep up with the times, it is impossible to say; nor do we yet know whether drugs will maintain their active therapeutic properties as well in the compressed tablet as in the well-coated pill-form. It is quite probable that the active principle of many drugs will deteriorate more or less in the tablet form, especially if exposed to the air.

There is a real objection to the employment of compressed tablets which is applicable to the employment of all medicines in the solid form, that is, absorption is not so certain nor so speedy when the drug is given in the solid as when it is given in the liquid state. Certainly, some medicines like quinine and salicylic acid are much more likely to have the desired therapeutic action if given in solution. It would, in fact, not be good practice in a severe case of intermittent to administer in pill or tablet form sufficient quinine to control the ague on account of the danger of provoking severe gastric irritation. Opium, especially, will often disappoint if given in pill or tablet form. At the same time the objection above made can be in large measure obviated by pulverizing the tablet before administration, and giving it in some menstruum in which it is soluble.

Another more serious objection has been raised in a leading article in the *Therapeutic Gazette*. Already the competition between manufacturing houses is great; the physician has an interest in buying his stock of drugs where he can buy them at the lowest price and there is a temptation to the pharmacist to fraud in the quality of his drugs, and an incentive to *short weight*. Hence the element of unreliability is introduced. But this objection is equally applicable to the dispensing of drugs by the retail apothecary. Changes have been known to occur in the putting up of prescriptions, when, for instance, strychnine has been substituted for quinine (because cheaper), and an important ingredient of the prescription has been left out because the druggist did not happen to have it in stock?

The “moral” plainly is this, that the physician in buying or prescribing his drugs must trust only such pharmacists as are of tried integrity and honesty.

Another objection to the dispensing of drugs by physicians is thus stated: “Where the cost of the prescription is borne by the patient, the physician will order the remedy which is most exactly indicated in the case without considering, in the majority of cases the cost; but where he himself has a temptation to look for a profit in the sale of his medicines, he will be tempted to prescribe the remedy which will yield him the largest profit.”

Here, again, the element of honesty comes in, and we can well conceive that between dishonest physicians and dishonest apothecaries the patient would be in a sorry plight. The contingency above hinted at is, we believe, more imaginary than real. It is the glory of the medical profession that it is not characteristically

a mercenary profession, and that physicians can generally be relied on conscientiously and honestly to do their duty, and give the right thing at the right time, whether it yields them the “largest profit” or not.

#### MEDICAL NOTES.

MEASLES at QUARANTINE.—The British Steamer *Lake Ontario* from Liverpool, arrived at Boston last week, with one hundred and one steerage passengers. Six families, including twenty-nine persons, were landed at Gallop's Island, eleven of them having the measles.

TUBERCULOSIS IN MASSACHUSETTS CATTLE.—It is reported that the Maine Cattle commissioners have discovered tuberculosis in cattle lately imported from Massachusetts, and have voted to prohibit the importation of cattle from that State.

INFLUENZA.—During the past fortnight epidemic influenza appears to have extended to a considerable extent, both in Europe and in this country. Reports in the daily press are often untrustworthy. The best evidence of the existence of the epidemic is often an increased death-rate, especially from pulmonary diseases. Most of the larger cities, as well as many smaller towns in the United States, appear to be afflicted to a greater or less extent. In Boston the death-rate for last week rose to twenty-six per thousand, a lower rate than is reported from several cities in Great Britain and the continent of Europe. An increase in the severity of the epidemic is reported from Germany, Russia and Austria. In Vienna several members of the royal family were attacked, three of whom have died. In New York, one hundred and forty-two members of the police force are on the sick list.

STATISTICS OF INFLUENZA.—The following appeal has been issued by Professor Leyden and Dr. Guttman, from Berlin, to the whole medical profession: “The report of the committee appointed by the Society for Internal Medicine to collect information concerning the influenza pandemic of 1889-90 is already in the printer's hands, and will be published very soon. As a new influenza epidemic is raging in various districts with great virulence, and it seems desirable to supplement the report with information regarding the time and place of its appearance, the character of the present epidemic, its duration, etc., our professional brethren are urgently requested to support the endeavors of the committee to the best of their ability, by sending us short communications on these points.”

ANTI-VIVISECTIONISTS.—The Society for the Protection of Animals from Vivisection, in London, having failed in their efforts to prevent the incorporation of the British Institute of Preventive Medicine, have memorialized the Home Secretary to refuse a vivisection license “next year and in all future years.” The memorial has 16,315 signatures, among whom are

fifty medical men, twenty-six peers, twenty peeresses, and fourteen bishops.

**A NATIONAL DEPARTMENT OF PUBLIC HEALTH.**—Senator Sherman has introduced a bill in the senate providing for the establishment of a department of public health under the charge of a medical officer, to be appointed from civil life by the President. This department shall obtain from consular officers at foreign ports all available information in regard to the sanitary conditions of such ports and places, and also all information accessible from State and municipal authorities of the sanitary condition of places in the United States. All the information gathered is to be embodied in the form of a bulletin, and transmitted weekly to the marine-hospital service, collectors of customs, and to State and municipal health officers. The department shall also procure and tabulate statistics relating to marriages, births, deaths, the existence of epidemic diseases, and all information relating to climatic and other conditions affecting public health. The department is to co-operate with State Boards of Health, the signal service, the medical department of the army, and other branches of the government, and utilize the results so as to make the new department a repository of public sanitary comfort.

**THE POPULATION OF ALASKA**, according to the recent census, is 31,795. Of these about four thousand are white, eighteen hundred mixed, twenty-three thousand Indian and two thousand Mongolian.

#### NEW YORK.

**TENEMENT-HOUSES.**—The Sanitary Superintendent has submitted to the Board of Health his report of the sanitary inspection of tenement-houses in the city for the year 1891. The inspections were completed in September. The report shows that there are 34,967 tenement-houses, and 2,391 rear tenement-houses, in which there dwell 276,505 families, comprising 1,225,111 persons, of which number 160,708 are children under five years of age. There are 4,297 stables in the city, in which are kept 62,208 horses. Of this number, 850 stables, containing 4,360 horses, are located adjacent to tenement-houses.

**CRITICISM OF BELLEVUE HOSPITAL.**—In the case of a patient who died at Bellevue Hospital on December 15th, of cerebral hemorrhage, the coroner's jury, which found that the man came to his death as the result of an accidental fall, added the following caution to their verdict: "And we desire to call the attention of hospital authorities, and particularly the staff of Bellevue Hospital, to the fact that persons who meet with accidents should not be sent to the alcoholic wards, unless it is beyond question a case of alcoholism; and it should not be assumed that the patient brought in by an ambulance is under the influence of liquor unless intoxication is apparent and established by competent physicians; inasmuch as persons meeting with accidents are sometimes given stimulants to revive them or to sustain them while being taken to the hos-

pital." In this instance, the patient fell down a pair of stairs, and on being taken to Bellevue Hospital, was placed in the alcoholic ward, though before death he was transferred to another ward. It was testified at the inquest that the man never drank.

**THE BRAIN OF THE BOMB-THROWER.**—The report of the examination of the brain of Norcross, the bomb-thrower, has recently been given out. The weight of the entire brain was found to be 1,210 grammes, about 100 grammes below the average, while that of the cerebellum was 154 grammes, or slightly above the average. After describing certain pathological appearances which were evidently of recent origin and due to the explosion, the report states that the left ascending parietal convolution, especially in its upper half, and the left first temporal convolution, especially in its anterior half, were greatly atrophied. The gray matter of the left ascending parietal convolution, was five millimetres in depth, and that of the left first temporal, four millimetres, while the gray matter of the first ascending frontal convolution was ten millimetres in depth, and that of the other convolutions varied from ten to seven millimetres. The left crus cerebri was four millimetres smaller than the right, and the left half of the pons was four millimetres smaller than the right. These abnormalities were all that were visible to the naked eye, but the opinion was expressed that they pointed towards insanity. The microscopical examination will be made after the brain has undergone the necessary hardening.

#### Miscellany.

**A SURGEON CANNOT BE SUED AS SERVANT AFTER THE ACQUITTAL OF THE HOSPITAL AS MASTER.**

JUDGE O'BRIEN in the New York Supreme Court Circuit lately dismissed the complaint in the suit of Windsor C. Hart against Dr. William T. Bull, to recover damages for malpractice. In 1884 Mr. Hart was operated upon by Dr. Bull at the New York Hospital. Hart claimed that the operation was not performed skillfully, and brought a suit against the New York Hospital, which was tried at Poughkeepsie in 1885, before Judge Barnard and a jury. The only question submitted to the jury on that trial was whether Dr. Bull performed the operation skillfully or not. The verdict on this issue of fact was for the hospital, and so, when the suit against Dr. Bull came to trial again, his counsel put in evidence the verdict and judgment of the former trial as a bar to recovery in the second suit. It was objected by the plaintiff that the parties to the two actions were not the same.

On the other hand, the position of the defendant was that, as the plaintiff elected to sue the Society of the New York Hospital on the ground that, as master, it was liable for the act of the defendant, its servant, and had had his day in court and secured a ruling that he (the plaintiff) was entitled to a verdict in that action for any negligence of Dr. Bull, he could not have another trial of the same issue by merely changing

defendants and suing the servant, after a jury had once decided against him on the merits of the question.

Judge O'Brien sustained the position of Dr. Bull's counsel, ruling that, upon the facts as they are now presented, the motion made by counsel for the defendant for a direction of a verdict in his favor should be granted. The action was originally brought against the New York Hospital for the alleged negligence of one of its doctors. The question then at issue was fairly and fully presented during the trial of the case as to the negligence of the doctor, and upon that there has been an adjudication in favor of the hospital.

Upon every principle, it is in the interest of justice, and in accordance with public policy, that after a man has had his day in court, and has been granted and accorded every opportunity of fully and fairly presenting his case, and after he has made his election and tried his case, that he should not be allowed to come in court and try the same question over again.

Concededly, the liability of the hospital in that case, if it was a liability at all, was a derivative one, being a legal liability resulting from the fact that it had connected with this hospital this doctor, the defendant in this case, no matter on what theory, whether upon the doctrine of election, or whether privy or party to the act or not.

This ruling, which seems in accordance with equity, and is in accordance with precedents in Maine and Rhode Island, saved the defendant an expensive trial.

### TREATMENT OF ACUTE CORYZA.

Now that the damp, chilly season has arrived when colds in the head are very prevalent, it is well to recall some of the favorite prescriptions for this complaint.

Capitan, in *Médecine Moderne*, No. 46, 1891, recommends the following powder, which, he says, arrests generally, almost immediately, a commencing coryza, if from the very onset the patient takes pains to snuff up a pinch into each nostril and draw it in deeply:

R Salol	. . . . .	1 gramme.	
Salicylic acid	. . . . .	20 centigrammes.	
Tannin	. . . . .	10 centigrammes.	
Powdered boric acid	. . . . .	4 grammes.	M.

Take a pinch every hour for half a day, and then discontinue the use of this snuff, for if it be persevered with, it may cause an eczematous eruption on the margins of the nostrils from the action of the phenic acid resulting from decomposition of the salol.

Another snuff-powder by the same writer is recommended as being similar in its action to the preceding, but less powerful:

R Powder of tale	. . . . .	5 grammes.	
Antipyrine	. . . . .	1 gramme.	
Polyboracic acid	. . . . .	2 grammes.	
Salicylic acid	. . . . .	25 centigrammes.	M.

This powder may be snuffed up the nostrils without fear of irritation.

M. Tessier, in the *Annales de Médecine*, indicates several formulae for the treatment of this affection. The following is a mixture for inhalation:

R Acid carbonic fort.	. . . . .	5 grammes.	
Liquor ammon. fort.	. . . . .	5 grammes.	
Water	. . . . .	15 grammes.	
Alcohol	. . . . .	15 grammes.	M.

Pour a few drops on blotting paper and inhale a few seconds. In some cases, chloroform or tincture of

camphor may be advantageously substituted for the water in the above.

Dobson, in the *Lancet*, May 31, 1884, advises respiration of camphor coarsely powdered and placed in a jug of boiling water as an effective remedy against coryza. "About one drachm of camphor should be added to half a pint of fluid and the steam thus impregnated should be inhaled slowly ten minutes every hour, repeating it three or four times, when the nasal inflammation will be much relieved. The jug containing the water as well as the face of the patient must be surrounded with a paper cone during the period of inhalation."

The following formula is recommended by Dr. Beverley Robinson:

R Poly. fol. belladonna	. . . . .	3 i.	
Poly. morph. sulph.	. . . . .	gr. ij.	
Poly. gum. acacia, ad.	. . . . .	3 ss.	M.

Sig. Use with the powder-blower for anterior and posterior nares.

This powder should be blown through the nose both anteriorly and posteriorly so as to coat over the mucous membrane lining the nasal passages very thoroughly. "Its most noticeable action is to diminish the congested condition of the interior of the nose, so as to permit freer passage of the inspired and expired current of air. This it does, doubtless, by contracting the small blood-vessels and lessening the amount of watery fluid which exudes from them into the cellular structure. Besides all three agents, morphia, belladonna and gum, are decidedly antiphlogistic in their action upon the inflamed pituitary."

Dr. Morell Mackenzie advises the following snuff, which is to be used from the commencement of the cold, but never longer than twenty-four hours.

R Morph. sulph.	. . . . .	12 centigrammes.	
Subnitrate of bismuth	. . . . .	3 gr. 50.	M.

To conclude: A person who is conscious of having taken a cold in the head, should take his room and resort for relief to some one of the measures of local treatment above given. For internal medication we do not think that much confidence is to be placed in the small doses of atropine or the large doses of quinine advised by some authorities. If there be a furred tongue and a deranged state of the *primæ viæ*, a saline laxative, a full dose of rhubarb and soda, or even a cholagogue cathartic may be indicated. Hourly doses (one drop) of tincture of aconite may be given, or two or three five-grain doses of acetanilid two hours apart, or two ten-grain doses of phenacetin at the same or a longer interval, if there be considerable fever and headache. It is worse than useless to take any other nourishment than a little hot liquid food till the acute symptoms have somewhat subsided. General diaphoresis will seldom be advisable for a simple coryza. Dover's powder is apt to disturb the stomach and constipate, and can seldom be required. Antimonials: iaborandi and pilocarpine are not to be thought of. A teaspoonful every two hours of aromatic spirits of ammonia, can do no harm; or two or three drops of the liquor morph. sulph. along with two and a half grains of ammonium carbonate every hour for six hours, and afterwards every hour and a half. According to Phillips, a few drops of the tincture of euphrasia officinalis (eye-bright) taken at the beginning of the attack of acute coryza, and repeated every two or three hours, will often abort it, and this treatment is endorsed by Dr. C. M. Garland in a former number of this JOURNAL.

## THERAPEUTIC NOTES.

**REMOVAL OF RUST FROM IRON.**—This, in the case of small objects, can be effected with surprising facility, according to the *Eisen Zeitung*, by wrapping a piece of beeswax in a cloth which is not too thick, and rubbing it over the iron surface, after the latter has been warmed. This will give it a thin coating of wax, which must then be rubbed off with another cloth, dipped in finely powdered salt.

**CHOLAGOGUE POWDERS.**—In the *Revue Générale de Clinique et de Thérapeutique* the following treatment for the relief of hepatic lithiasis is given.

R Benzoin of sodium . . . . . 55 gr. lxxxv.  
Salicylate of sodium . . . . . gr. viij. M.  
Powdered nux vomica . . . . . gr. viij. M.

Sig. This is to be divided into twenty powders. One powder three times a day for two months.

**IODIDE OF POTASSIUM IN ANGINA PECTORIS.**—Dr. Lauder Brunton<sup>1</sup> in a paper on "Cardiac Pain and Angina Pectoris," after speaking of the value of nitrite of amyl, nitro-glycerine, nitrite of sodium, etc., as agents by which the blood pressure may be rapidly diminished and the attacks of angina relieved, states that "first and foremost, amongst the drugs that are really efficient in tending to prevent the recurrence of the attacks in angina, comes iodide of potassium in doses of five to thirty grains three times a day."

## Correspondence.

## THE CAUSE OF THE ERRATIC COURSE OF SOME BULLETS.

STERLING, COLO., December 10, 1891.

MR. EDITOR:—The case of pistol wound of the head reported by Dr. E. H. Bradford in the *JOURNAL* of December 3, 1891, shows how strangely a bullet may act under some circumstances. It is possible that the following remarks may throw some light on the matter.

With a rifle of heavy calibre and a comparatively large charge of powder, the ball is impelled with such force that it pierces even tolerably firm wood without material deviation from its path. I have, with a rifle of .40 calibre, and using seventy grains of powder, shot through a standing spruce tree of fourteen inches diameter without stopping the "scream" of the ball, and leaving an absolutely straight track. It is needless to say that nothing in the human frame could do much toward causing a ball of such momentum to deviate from its course. On the other hand, I have twice known a ball fired from a weapon of the same calibre, and using sixty grains of powder, to be found in the body of a willow-grass, a fowl about the size of a small hen. Let us see why the results should be so disproportionate.

In order to do fairly accurate shooting, it is necessary to have a well-made weapon, thoroughly clean and properly loaded. Almost all the anomalous cases we meet with in shooting are due to some deficiency in one of these conditions. Let us first consider the weapon.

The country is flooded with cheap guns and revolvers. For anything like accurate shooting these poorly-made arms are utterly worthless. The material is of the poorest quality, and the workmanship is poorer yet, so that most of the gas generated by the burning of the powder is lost by leakage about the defective joints. It should be borne in mind in this connection, that the better quality of guns are warranted airtight at the joints, to insure the retention of all the gas and consequently hard and accurate shooting. Then the interior polish, if there be any, is so poor that

the barrel cannot be kept clean, and without this it is not possible to have accuracy, for the effect of the rifling is lost. The object of this rifling is, of course, to keep the ball in rotation so that its longitudinal axis may not change, for, if it does not rotate in this way, the long ball commonly used tends to revolve around a transverse axis, and it then loses its accuracy and force. After the ball loses its velocity, contact with any obstacle which deviates it from its path produces a similar result.

So delicate a matter is this rifling, that it is well known to sportsmen that a very little dirt in the muzzle will ruin the accuracy of a gun. I once tried a new Winchester rifle, and found that I was unable, with a rest, to strike a two-foot circle at forty feet distance. Examining it, I found a spot of rust the size of a pin-head so near the muzzle that in cleaning the weapon I had overlooked it. Removing this, it did excellent shooting. Even an apple-seed, moistened with saliva and surreptitiously placed just inside the muzzle of a rifle has caused a good shot to lose a match.

I once used some cartridges loaded with powder so foul that after firing the gun four or five times it became so filled up in the "rifles" that the ball would strike sideways at a distance of thirty feet, so that it was necessary to clean it after every shot while using those cartridges. The effect of the rifling was entirely lost, and the long ball revolved around a transverse axis. I once had a "bull-dog" revolver that, after two or three shots, would throw the ball as often sideways as endwise. The same cartridge, when fired from a Colt or Smith & Wesson revolver had much greater penetration, because of the closer confinement of the gas and the better rifling.

Next, as to the ammunition. It should be remembered that gunpowder is not a true explosive, but simply a substance which burns with extraordinary rapidity. If a weapon be loaded with powder too fine or too coarse, the shooting will be poor. If, in a heavy rifle, one should use powder as fine as that used in the small pistols, he would do very uncertain shooting, even at fifty yards, while the recoil would be excessive. The powder would burn with such rapidity in this case that the ball would scarcely have time to fairly start before the combustion would be completed. The gas would not act on the ball, as it should do to insure theoretically perfect shooting, with increasing force as it approached the muzzle, but with diminishing force, much of the power being worse than wasted in the excessive recoil.

If, on the other hand, the powder be too coarse, it is not wholly burned before the ball leaves the muzzle, but is blown out unburned, and its force consequently wasted. These unburned grains may be easily demonstrated by shooting over clean snow.

Then, again, the muzzle may be so obstructed that the shooting becomes ineffective. If snow accidentally obstructs the gun, and this is a very common accident, it is not simply pushed out by the advancing column of gas, but is compressed, and some part of the barrel commonly gives way. The force which should propel the ball is pretty well dissipated and the latter has no momentum, as it should have. The ball may also have a low initial velocity from dampness or other form of deterioration in the powder.

Once in a while we see reported cases in which a would-be suicide attempts his life by placing the muzzle of his weapon directly in contact with his person, and then firing. Even if the pistol be sufficiently well made to prevent the gas from finding exit around the joints, the ball may not even penetrate the skin. In a recently reported case of this nature, in which the man attempted to shoot himself in the abdomen, the ball dropped harmlessly to the floor. I once knew of a calf being shot by a trap-gun set for a bear, the ball barely penetrating the skin. The cause was probably the same as that in the case quoted.

If the gas escapes freely about the joints, but little penetration is secured under any circumstances. I have known of three instances in which the joints were so loose and the arm so foul that three or more bullets lodged in the barrel before the alleged sportsman using the weapon found out

<sup>1</sup> Practitioner, October.

why he could not see where he struck, the gas escaping completely at the breach.

In the case of the grouse mentioned, one of several causes may have operated to stop the bullet and cause it to remain in the bird's body. The powder may have been poor, the gun foul, the muzzle obstructed (although this would probably have destroyed the aim), or, most likely of all, the ball may have struck the ground before it did the bird, losing most of its force and becoming so flattened that it presented a greater surface and therefore was more easily stopped. The two latter causes in combination are the most probable ones.

When any of these causes lessen the velocity of the ball to such an extent that it has not sufficient force to go directly through whatever is before it, it will be more or less deflected from its course according to the nature of the obstruction. No bone in the human body could, by any possibility, deflect from its course the ball from the .40 calibre Winchester rifle if it were properly loaded, and yet we all constantly see cases in which the bullet from some ill-made revolver is completely turned from its track by a tendon or a rib. Every surgeon sees the curious cases where the ball follows up the tendons of the forearm or travels around the chest-wall. But he never sees them where a heavy rifle properly loaded is used, unless, indeed, it be from a spent ball, and such a possibility is to be borne in mind. I have known of several instances of a ball from a pistol following around the skull under the scalp when fired at close range, and yet, with the rifle mentioned, I cut a groove a third of an inch deep in the skull of a grizzly bear at nearly a quarter of a mile distance, and that when the ball impinged at an angle not greater than four or five degrees. Again, two months ago, I cared for a young man who accidentally shot himself in the back with a .45 calibre, government rifle, the ball striking the 11th rib at quite an acute angle. It was not apparently deflected from its course in the slightest, but, passing through the body, made so much noise in the air 500 yards away, as it passed over the house of a ranchman, that the latter thought some one was shooting at him. Upon investigating the matter, he found the injured man and cared for him.

In the case quoted by Dr. Bradford, we may conclude that probably one or more of the following causes operated to produce the unusual position of the ball, namely: Poor construction of the weapon; bad condition of it as regards cleanliness; excessive fineness or coarseness of the powder; dampness or other deterioration in its quality; obstruction of the muzzle, or the placing of it in contact with the skin.

In any case, the initial velocity and the momentum of the ball must have been very low, and it evidently was deflected by obstacles through which it should ordinarily pass without difficulty. In all probability, the first, second and possibly the last of the reasons mentioned were responsible for the strange action of the ball. After all has been said, however, I must admit that it would not have seemed possible for the bullet to have turned around in passing through so short a space. Very truly yours,

J. N. HALL, M.D. (HARV.)

## HOW LONG SHOULD A CONVALESCENT FROM DIPHTHERIA BE ISOLATED?

Boston, December 18, 1891.

MR. EDITOR:—*Apogee* of Dr. S. W. Abbott's excellent paper lately published in the *JOURNAL* (November 26th and December 3d), allow me to cite the following case which came under my observation a few days ago. It shows the danger of diphtheria being disseminated by cases supposed to have recovered from the disease and to be free from the poison. Two children of a family living in South Framingham were taken sick with the disease. About two weeks later the father was attacked. All recovered, the children becoming well first. When the father was supposed to be well, about nine days from the date of his "sitting up," the family came to Boston to make a visit to a relative.

In the family of the latter was one child. One week after the arrival of the visitors, the child was attacked with diphtheria and died. Inquiry elicited the fact that one of the visitors—the father—could not have been perfectly well; for his "voice was thick," so much so that his wife constantly asked him how his throat felt, during the first days of his visit.

I think there can be little doubt of the connection between these cases.

If my memory serves me rightly, an outbreak of diphtheria in a hotel at Nantucket, some years ago, followed the arrival of a person just recovered from diphtheria, and pronounced well by the attending physician. One of the persons who had the disease at Nantucket, when supposed to be well, removed to a hotel in a town not far from Boston. Shortly after arrival, many of the people in the hotel were attacked, and it was found necessary to close the hotel.

Before closing, and as illustrative of another mode of contagion, I may mention the remarkable coincidence (!) (with which I am painfully familiar) of the occurrence of three cases of diphtheria in a family, closely following the advent of a nurse who had just come from attendance on a fatal case. Of these three cases one died.

The determination of the time when danger from contagion after recovery is passed, is a practical question of great importance. I think that evidence goes to show that the poison is retained in the mucous membrane longer than is generally considered to be the case. In lieu of definite knowledge, I have adopted the arbitrary rule of advising quarantine precautions for one week after the patient appears to be perfectly free from disease. This seems to me a fairly safe rule and one that is desirable.

Yours truly, MORTON PRINCE, M.D.

## RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, DECEMBER 5, 1891.

Cities.	Estimated population for 1891.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute-ting fevers.	Scarlet fever.	Typhoid fever.	Diphtheria and croup.

Deaths reported 3048; under five years of age, 1069; principal infectious diseases (small-pox, measles, diphtheria and croup,

diarrhoeal diseases, whooping-cough, erysipelas and fevers) 467, acute lung diseases 494, consumption 355, diphtheria and croup 205, typhoid fever 86, scarlet fever 70, diarrhoeal diseases 38, cerebro-spinal meningitis 19, measles 14, puerperal diseases 11, malarial fever 8, whooping-cough 8, erysipelas 7.

From diarrhoeal diseases Chicago 9, Brooklyn 6, New York, Philadelphia and Washington 4 each, Baltimore, Milwaukee, Nashville and Worcester 2 each, Portland, Lawrence and Newton 1 each. From cerebro-spinal meningitis New York 4, Chicago, Baltimore and Gloucester 3 each, Washington and Worcester 2 each, Pittsburgh and Quincy 1 each. From measles New York and Chicago 6 each, Brooklyn and Baltimore 1 each. From puerperal diseases New York 6, Chicago 2, Philadelphia, Milwaukee and Springfield 1 each. From whooping-cough Chicago 3, Nashville 2, New York, Milwaukee and Springfield 1 each. From malarial fever Brooklyn 5, New York, Baltimore and Cleveland 1 each. From erysipelas New York 3, Brooklyn 2, Chicago and Washington 1 each.

In the twenty-eight greater towns of England and Wales with an estimated population of 9,435,108, for the week ending November 28th, the death-rate was 20.5. Deaths reported 3,502; acute diseases of the respiratory organs (London) 114, whooping-cough 114, measles 94, fever 59, diarrhoea 47, diphtheria 41, scarlet fever 37, small-pox (Birmingham) 1.

The death-rates ranged from 13.4 in Portsmouth to 28.3 in Plymouth, Birmingham 20.1, Bradford 16.8, Halifax 20.1, Hull 14.5, Leeds 18.6, Leicester 19.0, Liverpool 24.6, London 19.9, Manchester 21.8, Newcastle-on-Tyne 31.1, Nottingham 17.7, Salford 21.8, Sheffield 21.8.

In Edinburgh 35.4, Glasgow 30.9, Dublin 30.3.

#### METEOROLOGICAL RECORD.

For the week ending December 5, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

#### OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 12, 1891, TO DECEMBER 18, 1891.

By direction of the acting Secretary of War a board of medical officers to consist of COLONEL BERNARD J. D. IRWIN, surgeon; LIEUT.-COL. CHARLES H. ALDEN, surgeon; MAJOR ALFRED C. GIBBARD, surgeon; FIRST LIEUT. ALFRED E. BRADLEY, assistant surgeon, is constituted to meet at Headquarters Department of the Missouri, Chicago, Ill., on the 1st day of February, 1892, for the examination of candidates for admission to the Medical Corps of the Army, and for such other business as the surgeon-general may desire to bring before it.

By direction of the acting Secretary of War, so much of paragraph 1, S. O. 265, A. G. O. November 13, 1891, as directs CAPTAIN EDGAR A. MEARS, assistant surgeon, to report to the commanding officer, Fort Mackinac, Mich., is revoked; he will proceed to El Paso, Texas, and on arrival there report for duty to LIEUT.-COL. JOHN W. BARTON, Corps of Engineers, member of the commission appointed for the location and marking of the boundary between Mexico and the United States.

LIEUT. COL. PHILIP G. WELLS, assistant surgeon, U. S. A., is ordered to proceed to New York for one month, with permission to apply for an extension of one month.

#### SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. A regular meeting of the Society will be held on Monday, December 28, 1891, at the Medical Library, 25 Beakton Place, at 8 o'clock P. M.

Dr. C. M. Green, "The Care of Pregnant and Puerperal Women."

Dr. G. C. Sears, "The Etiology of Acute Pleural Effusions." Election of Committee to nominate officers for the ensuing year.

G. C. SEARS, M.D., Secretary.

#### RECENT DEATHS.

LUCIEN DAMAINVILLE, M.D., died in New York, December 15th, aged fifty-two. He graduated from the Long Island College Hospital in 1861, was for some time visiting physician to the French Hospital, and since 1867, has been one of the police surgeons of New York City.

EDWARD SAWYER, M.D. (Harv., 1845), M.M.S.S., died in Bridgewater, December 21st, aged fifty-three. He had been in Bridgewater since 1867, where he has held several public offices.

SAMUEL CURTIS ROBINSON, M.D. (Yale, 1855), of Brooklyn, N. Y., died December 22d, aged sixty-one.

ROSSELL P. COLLIN, M.D. (Coll. P. and S., N. Y., 1879), of New York City, died December 22d.

GIOVANNI SPANTIGATI, M.D., of Turin, Italy, died November 13th, aged fifty-five. He was "medico primario" of the hospital of San Giovanni. During the Franco-German War he became well-known in the medical department of the French Army, and received the highest honors from the French Government.

PIERRE BAILLARGEON, M.D. (Harvard, 1840), of Quebec, Senator in the Canadian Parliament, died December 15th, aged eighty-eight.

FRANZ CHRISTOPH VON ROTHMUND, M.D., formerly professor of surgery in the University of Munich, died early in December, aged ninety-two.

SIR JAMES RISON BENNETT, M.D., formerly President of the Royal College of Physicians, London, died December 14th, aged eighty-two.

UNSUSPECTED HEART-DISEASE.<sup>1</sup>

BY HERMAN F. VICKERY, M.D.,

*Instructor in Clinical Medicine, Harvard University; Physician to Out-Patients, Massachusetts General Hospital.*

SIR ANDREW CLARK reported, before the British Medical Association, in 1887, 864 cases which he had seen during the years 1873 to 1886 inclusive, suffering from chronic valvular disease of the heart, "which was not indicated by symptoms, and had not sensibly interfered with the health."<sup>2</sup>

Every practitioner must have been struck with the occasional appearance among his patients of similar cases; and I venture to report some which have lately occurred to me, with the purpose, not so much of endeavoring to establish a fact already well known, as to enforce its practical bearing. In my cases the patient had no idea of any cardiac trouble, and indeed some of them were such that the physician would not be led by the rational signs to regard organic heart-disease as the most probable diagnosis.

CASE I. Mr. I. W. H., aged fifty-one, was a retired business man who used very strong tobacco to excess. He described himself as a "tobacco worm." This gentleman was fond of an out-door life, and in October, 1889, while making a "carry" in the woods with a rather heavy load upon his back, he experienced a sudden pain in the jaws, severe enough to make him stop, whereupon the pain ceased; but it recurred when he resumed his march. From that time to the time when I first saw him, seven months later, the pain was felt upon either excitement or exertion; and there had been added to it a palpitation of the heart. The double aortic lesion which was found upon examination had not, in any way, interfered with his pleasures or exertions until the time when this neuralgic pain first appeared.

CASE II. Mr. C. G., aged thirty-three, a contractor, experienced an accidental injury for which he was brought into the Massachusetts General Hospital, November, 1890, coming under the care of Dr. C. B. Porter, who kindly permits my mention of the case. Physical examination revealed, beside his surgical injuries, slight lateral enlargement of the heart, with a systolic apex murmur transmitted into the axilla, and a to-and-fro murmur in the second interspace on the left. In this case no symptoms had pointed to the heart. But for the accident, it is not probable that the patient would have come under medical observation.

CASE III. J. R., aged nineteen, fell down stairs and injured his right ankle ten days before he called upon me. He was confined to bed for nine days, but on arising he noticed trouble about the heart, having never had such symptoms before. He came to me supposing that the fall had caused heart-disease. On investigation, it was found there was no history of rheumatism or scarlet fever; but the patient had had small-pox when a child. The heart's apex was in the fifth space outside of the nipple. There was enlargement of the heart a finger's breadth to the right of the sternum, a presystolic thrill at the apex, a presystolic and systolic apex murmur, and a double murmur over the aortic region with a typical "crural

tone" in the femoral artery, — a condition of things evidently chronic.

CASE IV. (Reported by the kind permission of Dr. F. C. Shattuck.) Mr. H., aged thirty-four, a gardener, complains of purpuric spots, and pain in the muscles of the legs. Otherwise he feels perfectly well and looks well, and his bodily functions are well performed. Examination, however, reveals a systolic thrill at the heart's apex, and a loud systolic murmur heard best in the fourth space on the left, but audible all over and even outside of the cardiac area. The pulmonic second sound is not accentuated, nor is the heart much enlarged. The murmur, which is somewhat rough in character, has persisted now for several months, and is in all probability due to mitral regurgitation well compensated.

CASE V. (Also reported by permission of Dr. F. C. Shattuck.) Herbert F., aged twenty-one, a farmer, had acute articular rheumatism four years ago; but, after recovery from that, he had done hard work and enjoyed excellent health until three days before entrance into the hospital with the symptoms of subacute rheumatism. Examination established clearly the existence of mitral regurgitation, referable not to the present, but to the first attack of rheumatism.

CASE VI. (Reported by the courtesy of Dr. H. C. Ernst.) D. O'G., aged twenty-six, teamster, comes to the out-patient department of the Massachusetts General Hospital, on account of an eruption of secondary syphilis. Although on questioning he states that he has some years previously undergone an attack of rheumatism which confined him to the bed, and for the last three or four months has had some dyspnea on exertion, he maintains that the only symptoms which led him to seek advice are connected with his venereal trouble. Examination shows an enlarged heart with a distinct presystolic thrill and presystolic murmur at the apex and accentuation of the pulmonic second, — mitral stenosis.

CASE VII. (Reported also by permission of Dr. Ernst.) William D., aged twenty-six, a butcher, complains of "pain in the kidneys," great thirst, cramps and dull aching pain through the legs at night, excessive appetite, frequent micturition and loss of twenty-two pounds weight. On later inquiry he acknowledges that four years ago he had an attack of acute articular rheumatism lasting three months, but he has never noticed any cardiac symptoms. This patient was brought to the medical clinic at the hospital as a case of diabetes mellitus, and with good reason; but the prominent pulsation of the temporal arteries in so young a man (twenty-six years) called attention to the heart, which was found to be hypertrophied and affected by both aortic and mitral incompetence.

CASE VIII. N. S., aged seventeen, was in the Massachusetts General Hospital November 13 to December 29, 1890, with uræmia; and on examination he was found also to be suffering from mitral regurgitation. In May, 1891, and again in October, 1891, the patient returned for observation, and no complaint of cardiac symptoms could be elicited, although the objective evidence of the heart lesion was still present.

CASE IX. John D., aged twenty-two, a waiter, had rheumatic fever four years ago. The reason for his seeking advice, in May, 1891, I have forgotten; but I am confident that it was no direct cardiac symptom. He had been ailing only two weeks. On examination a double mitral lesion, with a thrill at the apex, and

<sup>1</sup> Read before the Section of Clinical Medicine, Pathology and Hygiene of the Suffolk District Medical Society, November 18, 1891.

<sup>2</sup> British Medical Journal, February, 1887.

an aortic regurgitation, were made out, and there were also moist râles above the right clavicle.

CASE X. William M., aged forty, complained that for one week he had experienced cough and pain in the chest. No other symptoms could be elicited. Examination disclosed moist râles in both bases behind, also a double aortic murmur and a systolic murmur at the apex transmitted into the axilla.

CASE XI. F. S., aged fifty-six, paper-hanger, has had a cough all winter, with little expectoration, and he also suffers from "sour stomach." The heart is irregular in action and the aortic valve is incompetent.

CASE XII. Daniel S., aged seventy-two, complains of being "sore all over" and "choked up in the chest." He coughs all night, with a mucous expectoration. Bread and tea are the chief diet. The pulse is irregular, feeble and intermittent. There is a faint systolic murmur at the apex, transmitted towards the axilla. Pulmonary oedema exists at the bases of both lungs.

Of these twelve patients, five had disease of both the aortic and mitral valves, four had mitral regurgitation, one had mitral stenosis, one had aortic regurgitation, and one had both stenosis and incompetence of the aortic valves. Of the 684 cases reported by Sir Andrew Clark, 41 per cent. had mitral regurgitation, 24½ per cent. had aortic stenosis, 14 per cent. had affections of both valves, 9 per cent. had mitral stenosis, 4½ per cent. aortic regurgitation, 3¼ per cent. aortic obstruction and regurgitation, and 2½ per cent. mitral obstruction and regurgitation.

According to his experience, therefore, we might infer that mitral regurgitation is the least unfavorable valvular disease, and next to it aortic stenosis; but different authorities differ widely about this question. Fagge regards aortic stenosis as of the least relative importance, followed by mitral stenosis, next to which—but separated by a long interval—come mitral regurgitation and aortic regurgitation. Striimpell believes that aortic regurgitation generally gives the best prognosis, that mitral insufficiency is rather worse, and that worst of all are mitral stenosis and aortic stenosis.

If we search for an explanation of these apparent contradictions, we shall find it in the all-important fact that every case of heart-disease must be judged independently. The crucial test for the heart is its ability to carry on the circulation. Now it is easy to see that the size of the leak or the degree of the stenosis may vary between great extremes, that the development of compensatory hypertrophy may be ample in a young and robust individual of good habits, and next to nothing in an old and syphilitic drunkard, and that a stationary lesion which presents no changes in the course of one or more years, is less to be feared than one which is still progressive. The names mitral stenosis, aortic regurgitation, and the like, tell only a part of the truth, and that not the most important. Myocardial degeneration without a murmur is a worse thing than valvular lesion with adequate hypertrophy. And although I do not here present such a case, the determination of the state of the cardiac muscle demands even more vigilance in physical examination than the condition of the valves. (It should be added perhaps, to avoid misunderstanding, that given a defect in the valves, the degree of cardiac hypertrophy is to some extent, a measure of the importance of that

defect. If compensation is good, the less the hypertrophy the more favorable the case.

The twelve cases reported by me had this one thing in common: for a considerable period of time they had had heart-disease and yet had been entirely unconscious of the fact. Some of them, indeed, did not have symptoms suggesting heart-disease to a physician, thus affording a striking contrast to the sufferers from functional disorders who so frequently demand a physical examination and who are so slow to be convinced that their hearts are not organically diseased.

The ordinary rational signs of heart-disease may be briefly enumerated as follows: dyspnoea, palpitation, precordial distress, headache, vertigo, cough and indigestion. Of my cases, one, it will be remembered, confessed on questioning that he had suffered somewhat from dyspnoea, although he asserted that the trouble was very slight. With this exception none of the patients presented the rational symptoms just enumerated, except cough (which was present in three cases) and indigestion (which was present in one case).

Of Clarke's 684 cases, 402 had digestive symptoms, 35 had headache, 17 had vertigo, 23 had bronchitis and seven had pulmonary congestion; so that really 487 might be said to have presented symptoms suggesting the possibility of cardiac disease; but even then, the large number of 197 remain, the correct diagnosis and proper treatment of which hung upon the physical examination.

The lesson to be gained from these observations is the necessity of thoroughness in the physical examination of every patient, so far as practicable. There are those who regard it a mistake to inform a patient as yet undisturbed by cardiac symptoms that he is the victim of a cardiac disease. Bristowe, for example, speaking in this connection says, "I am sometimes inclined to think it is a pity there are physicians. Many persons would lead a happy life enough but for them. If a patient has a heart-trouble, he does not wish to learn the fact." My own view is that, under ordinary circumstances, the earlier such a discovery is made by the physician and communicated to the patient, the better. This affords a fair chance for averting cardiac failure. A sensible patient, properly advised as to his physical limitations, may be able to lead a long, happy and useful life, whereas unwarned he might soon collapse into hopeless invalidism.

#### A REPORT OF 392 CASES OF INTUBATION AND 139 CASES OF TRACHEOTOMY DONE AT THE BOSTON CITY HOSPITAL.<sup>1</sup>

BY W. H. PRESCOTT, M.D., AND JOEL E. GOLDTHWAIT, M.D., BOSTON.

INTUBATION for the relief of laryngeal obstruction in diphtheria was done at the Boston City Hospital, for the first time, on December 31, 1886, and from that time up to January 1, 1891, it has been done in 392 cases. During this time tracheotomy has been done 139 times; 82 of these being primary operations, 36 after intubation, and 21 after attempted intubation.

In the report of cases of tracheotomy made by Drs. Lovett and Munro,<sup>2</sup> were included all operations per-

<sup>1</sup> Read before the Surgical Section of the Suffolk District Medical Society, November 4, 1891.

<sup>2</sup> Lovett and Munro: American Journal Medical Sciences, July, 1887.

formed previous to January 1, 1887, while in this paper all operations (both intubations and tracheotomies) since that time are reported. During the first year after intubation was introduced at the hospital, it was done only occasionally, and on picked cases; while during 1890 it was practically the only operation, tracheotomy being reserved for exceptional cases or was done as a secondary operation.

The writers are indebted to the visiting surgeons for permission to report these cases.

#### INTUBATION.

The details of the operation will not be entered into in this paper; suffice it to say, that, while at first the operation was done with the patient in the sitting posture, at present it is done with the patient lying down with a small pillow under the neck. In this position the operation can be done more easily, and the child more easily held.

Of the 392 cases, 312 died and 80 recovered (20.41%); 36 cases were followed by tracheotomy, with three recoveries; there were 21 cases in which intubation was attempted, and where either the tube was not inserted or else the child did not breathe after insertion, so that tracheotomy was immediately performed, and these cases will be included in the report of the tracheotomies. Over ten per cent. of all the cases were moribund upon entrance to the hospital.

The age of the child has a very decided influence upon the chances of recovery, as in tracheotomy. This is shown in the following table:

Age.	Cases.	Recov.	Per cent.
Under 3 years . . . . .	123	18	14.63
3-5 years . . . . .	143	43	29.65
6-10 years . . . . .	55	17	30.90
10 years and over . . . . .	10	2	20.00

The average age of the cases that recovered was four years and six months, of fatal cases three years and nine months, and of all three years and eleven months. One case was twenty-seven years old, three were seven months; all died.

The early operation, after the appearance of laryngeal symptoms, does not seem to have the same effect on the recoveries as in tracheotomy<sup>a</sup> for

In 210 cases operated upon the 1st day there were 42 recoveries.

60	"	"	2d day	"	15	"
22	"	"	3d day	"	10	"
10	"	"	4th-9th days	"	3	"
88	where the time could not be ascertained.					
					10	"

Two were hoarse and croupy for two weeks before operation (both died). One was intubed four hours after the first symptoms, which were laryngeal. The average time of operation was thirty-six hours after the appearance of laryngeal symptoms.

The average length of time that the tube was worn in those that recovered was five days and eighteen hours; the average in the fatal cases was two days and three hours; while the longest time a tube was worn was twenty-three days. The age has a decided influence upon the length of time that a tube is required, the younger the child the longer it must be worn. This is shown in the following table:

Age.	Average time tube was worn.
1-2 years . . . . .	9 days and 19 hours.
2-3 years . . . . .	8 days and 4 hours.
3-4 years . . . . .	5 days and 4 hours.
4-5 years . . . . .	4 days and 11 hours.
5-6 years . . . . .	1 day and 19 hours.

There were too few of the other cases to make any averages.

**Complications.**—Eleven cases developed measles; five recovered. Three cases developed scarlatina; one recovered. Nephritis, as shown by albuminuria and casts, was a frequent complication, but the notes are not full upon this point.

**Accidents.**—Numerous accidents occurred; some unavoidable, some due to faulty instruments, some to lack of skill. In ten cases the tube was plugged with membrane; and in two spasm of the jaw occurred, making tracheotomy necessary. In three cases death occurred during the attempt to insert the tube; and two died during choking spells before relief could be given (in one case relief was obtained by the nurse holding the child up by its feet and slapping it on the back, forcing the tube out). Four stopped breathing after reinsertion of the tube (it having previously been worn with relief), and tracheotomy was done; in two the introducer broke (owing to a defect); in two, insertion of the tube caused convulsions; in two, the tube was drawn into the bronchi, and these cases are reported in detail:

**CASE I.** Female, aged fifteen months, entered hospital, having been sick one week, and with laryngeal symptoms for six days. She was immediately intubed with a "two-year old" tube. Tube worn three days, and then coughed up; replaced in twenty minutes; coughed up again next day, and replaced immediately; worn two days, and again coughed up. A three to four year old tube was now passed, and worn five days; then removed and replaced. Soon after this the breathing suddenly became labored; and as the tube could not be felt in the larynx, tracheotomy was done (the intubation tube could not be felt in the trachea). A quiet night was spent, and in the morning the tube was felt in the left bronchus; it was removed after great difficulty; but the patient failed rapidly, and died quietly, probably from exhaustion.

**CASE II.** Male, aged thirteen months. About seven weeks before entrance was suddenly taken with choking, and became cyanosed. Tracheotomy was done next day, and the symptoms relieved; several attempts were made to remove the tube, and all failed. With the laryngoscope the larynx could not be seen, owing apparently to paralysis of the epiglottis. One week after entrance there were several severe attacks of dyspnea, which were relieved by passing a longer tube (tracheotomy). Twenty-three days after entrance an intubation tube was passed with some difficulty, owing to the flabby epiglottis; comfortable; fed by enemata for two days, and then by mouth. Six days after intubation (the child having been well and comfortable) several unsuccessful attempts were made to extract the tube; in about half an hour there was a severe attack of dyspnea, and as the tube could not be felt in the larynx, tracheotomy was done. The tube could not be felt in the trachea. On examining the chest, the breathing on the right side was loud, high-pitched and tubular; on the left, the entrance of air was heard only through the first half of inspiration, while expiration was diminished and low in pitch. Breathing became labored, and death took place forty-eight hours after the disappearance of the tube. At the autopsy, the tube was found projecting from the right primary bronchus, with its head resting upon the left side of the trachea in such a way as to partly cut off the air from the left chest.

<sup>a</sup> Lovett and Munro: American Journal Medical Sciences, July, 1887.

Its head was two and one-quarter inches below the tracheotomy wound. The left lung showed in its lower lobe a small area of dark-red consolidation. Nothing else remarkable was noted, except that the epiglottis was long and flabby.

The table of the causes of death which is as follows, is not very reliable, as it is made up from the clinical records, there being very few autopsies:

Sepsis . . . . .	149
Extension . . . . .	75
Heart-failure . . . . .	37
Broncho-pneumonia . . . . .	27
Exhaustion . . . . .	9
Complications . . . . .	9
Asphyxia . . . . .	3
Suppression of urine . . . . .	2
With convulsions . . . . .	1
	312

Broncho-pneumonia was more common than the figures would indicate, it being a complication in many cases of sepsis and extension. It is impossible to decide whether pneumonia from the inhalation of food was common or not, although the symptoms of broncho-pneumonia often seemed to follow the ingestion of liquids; this would be a less doubtful point if the same thing did not happen after tracheotomy.

#### TRACHEOTOMY.

Tracheotomy was done 139 times; 82 being primary, with 11 recoveries; 36 following intubation, with 3 recoveries; and 21 following attempted intubation, with 2 recoveries; 19 cases were moribund at the time of operation.

In comparing the ages it is true, as with intubation, that the younger the child the less favorable is the prognosis, as is shown in the following table:

	Cases.	Recoveries.
Under 3 years . . . . .	45	4
3-5 years . . . . .	58	7
6-10 years . . . . .	19	5
Over 10 years . . . . .	10	0
Unknown . . . . .	7	0

In 53 cases operated upon the first day after the appearance of laryngeal symptoms, there were four recoveries; in 31 cases on the second day, six recoveries; in 16 cases on the third day, two recoveries; in 7 cases on the fourth day, one recovery.

The character of the discharge from the tube was of great value in prognosis; for in 34 cases where the discharge was thin and abundant, there were 13 recoveries; in 16 cases where the discharge was gummy at some time, there was one recovery; and in 14 cases where the discharge was suppressed at any time, there were no recoveries. The average length of time the tube was worn in those cases that recovered, was nine days and five hours; and in all cases three days and three hours. (This average does not include the case in which a tube is still worn, two and one-half years after operation.) Two cases had diphtheria of the wound, one recovered. Five had convulsions, six were delirious, and two had subcutaneous emphysema; all died.

*Cause of death.*—Sepsis, 11; extension, 17; heart-failure, 18; broncho-pneumonia, 1; complications, 3; exhaustion, 2; asphyxia, 2; died on the table, 6.

Broncho-pneumonia, as in intubation, was more common than the figures would indicate, it being present in many cases of sepsis and extension; but an ab-

solute diagnosis was impossible owing to the lack of autopsies.

*Treatment.*—Each patient upon arriving at the hospital, unless requiring immediate operation, is given steam for inhalation, and hot poultices are applied about the throat. Many times by these means, the spasm and dyspnoea are relieved; while in a certain class of cases, instead of relief following, the dyspnoea is increased. Occasionally relief is obtained by the use of mustard pastes where the poultices had been unsuccessful. Paregoric, in small doses frequently repeated, has been followed by marked relief in numerous cases where the dyspnoea has been of a spasmodic character. Numerous throat sprays have been used with varying results, but the hydrogen-peroxide spray has been on the whole the most satisfactory, and combined with the insufflation of iodoform has been very efficacious in the foul necrotic cases.

No one line of interval medication has been carried out for a sufficient length of time to warrant any definite conclusions, except that corrosive sublimate has been used quite freely and has given quite satisfactory results, for in 95 cases of intubation in which it was used, there were 27 recoveries (27.84%). Turpentine emulsion (ten to fifteen drops spirits of turpentine to one drachm cod liver oil) at times gave marked temporary relief to the dyspnoea. Alcoholic stimulants have been used freely in all the cases. The feeding is very important, especially after intubation. Occasionally the patient is able to swallow food (including liquids) without difficulty with the intubation tube in place; but, as a rule, the swallowing of food, especially liquids, is followed by coughing and a good deal of discomfort. In these cases the most satisfactory mode has been the administration of soft solids by the mouth, with the patient lying down with the head lower than the rest of the body, combined with warm water enemata for the thirst. Cracked ice by the mouth is also allowed. Early extraction of the tube, even if reinsertion be necessary, is done occasionally for the purpose of feeding.

*Ultimate Results.*—Thirty-seven of the 80 cases that recovered after intubation were seen at least a year and a half from the time of operation; the other cases were not found. All of these 37 were in good health, in perfect voice, and presented nothing that would indicate any former ulcerative process due to pressure of the intubation tube. Ulceration and necrosis from pressure of the tube have been spoken of by various writers as among the dangers of intubation.

In considering the statistics developed in this paper, it is of interest to compare them with the results obtained by the various writers; and the first thing that attracts attention is the high rate of mortality, especially in the tracheotomy series, but it is only fair to remember that in this series the operation was reserved for the more severe cases. Ten per cent. of all the cases reported were moribund at the time of entrance to the hospital.

#### INTUBATION.

Authors.	Cases.	Recov.	Per cent.
American . . . . .	1,765	605	34.27
French and German . . . . .	692	199	33.6
English . . . . .	66	23	34.85

These, with the 392 cases of the present series, make a total of 2,815 cases, with 32.2% of recoveries. (So far as was possible, the cases reported in Brown's series of 2,700 cases are not included in this report.)

## TRACHEOTOMY.

	Cases.	Recov.	Per cent.
Lovett and Munro's Series <sup>1</sup>	21,853	6,135	28.
Romme's Series <sup>2</sup>	1,559	605	38.8
American authors	367	98	26.7
English authors	23	9	39.13

These, with the 139 cases reported in this paper, make a total of 23,941, with 28.67 % of recoveries.

## CONCLUSIONS.

Three hundred and ninety-two cases of intubation and 139 cases of tracheotomy have been reported, with a mortality-rate of 79.59% in the former and 88.5% in the latter; 2,815 cases of intubation and 23,941 cases of tracheotomy have been collected and analyzed, showing comparatively no difference in the mortality-rate of the two operations. The results depends more upon the nature of the epidemic than upon the operation. With intubation the results depend more upon the skill and experience of the operator than with tracheotomy.

Thirty-seven cases were seen at least a year and a half after recovery from intubation, with perfect voice, and with nothing that would indicate any ulceration from pressure of the tube.

## Clinical Department.

TWO CASES OF APPENDICITIS, ONE ASSOCIATED WITH UTERINE FIBROID, THE OTHER WITH PREGNANCY.<sup>1</sup>

BY S. J. MIXTER, M.D.,

Visiting Surgeon, Carney Hospital; Surgeon to Out-Patients, Massachusetts General Hospital; Demonstrator of Anatomy, Harvard Medical School.

THE following cases of appendicitis are reported because they present a point of interest that the reader has not met with, either in the other cases operated upon by him, or among those reported by others. In both cases an enlarged uterus was present, and in both, the correct diagnosis was not made until the operation or the day before it. When an attack of peritonitis occurs in a patient having an abdominal tumor, one is always apt to ascribe it to the tumor. These cases show that the appendix should also be considered as a possible cause of trouble.

**CASE I.** Mary M., over fifty years of age; married twenty-three years; no children; always strong and well. Three years ago noticed a gradual enlargement of abdomen, which has continued to time of operation. Flowing slight at first, but during past year quite profuse. Within a year has had several attacks of abdominal pain; three months before admission to hospital had a similar attack, but severer than previous ones. A physician, was now called for the first time, and found the patient "almost in a state of collapse," with general abdominal tenderness and distention, vomiting, and other symptoms of severe peritonitis. The patient gradually recovered from these acute symptoms, but the abdominal tumor then detected, gradually increased in size; there was constant pain, more flowing, and increasing weakness.

She was admitted to the Carney Hospital July 1, 1891. On examination I found a tumor reaching

above the umbilicus; it was hard and apparently closely connected with, or a part of, the uterus, and firmly fixed in right iliac fossa.

The next day I opened the abdomen, intending to remove the tumor, probably a uterine fibroid. After tying the left broad ligament, the tumor could be more easily turned out and the adhesions on the right side reached. While separating these adhesions the finger opened a cavity containing a considerable amount, perhaps four ounces, of foul pus, and projecting into the abscess cavity was the swollen and inflamed appendix. The pus escaped into the peritoneal cavity, which was washed out with hot salt solution. The uterus was then removed at its vaginal insertion, and the stump dropped back. The appendix, together with a large mass of inflammatory tissue, was removed, the stump of the appendix being simply tied with silk; and a very large amount of iodoform gauze was packed into the pelvis and about the cecum.

The gauze was removed on the third day. Recovery was rapid and uneventful, the patient being discharged well in about six weeks.

**CASE II.** Rose M., thirty-two years old, married. Four months ago, when seven months pregnant, had severe pain in abdomen, tenderness, fever, etc., and was delivered of a dead fetus. Did not recover well; pain and other abdominal symptoms persisted, and she was confined to her bed for three months. The pain was so severe that morphia was required every night. After being about the house for a short time she had an exacerbation of the symptoms that had never disappeared, and was admitted to the gynecological ward of the Carney Hospital. Dr. Johnson, on duty in that department, asked me to examine her with him, under ether. An ill-defined tumor could be seen and felt, extending from the iliac fossa to the ribs, and reaching almost to the linea alba. Nothing abnormal could be found in the pelvis.

The patient, having been transferred to the surgical service, was operated on September 23, 1891. An opening was made in the linea semi-lunaris, and a hard mass could be seen and felt outside the ascending colon and about the cecum, the bowel being pushed toward the median line. This mass was plainly inflammatory; and on separating the cecum from it, an abscess, situated at the brim of the pelvis, as large as a walnut, was opened, and in it were found two hard faecal concretions. Extending upward from this cavity, and outside the colon, could be followed a sinus; in the midst of the inflammatory mass and running parallel to it and behind it could be seen the appendix. This sinus was followed up by tearing with the finger until the kidney was reached. Just over the lower end of the kidney was fixed the much-thickened and perforated end of the appendix. This was the starting-point of the sinus, which ended in the abscess cavity spoken of just at the brim of the pelvis. The appendix was separated from its adhesions, cut off above to the bowel, and its invaginated end closed with a continuous silk suture. The cavity was packed with iodoform gauze.

Patient had a sharp attack of bronchitis following the operation, but had no peritoneal symptoms, and was discharged well in less than five weeks.

# OPERATION FOR THE RADICAL CURE OF HYDROCELE AND INGUINAL HERNIA.<sup>1</sup>

BY FRANCIS S. WATSON, M.D.

OPERATIONS (*a*) for the radical cure of hydrocele, by excision of the tunica vaginalis; and of (*b*) inguinal hernia, by McBurney's method; performed at the same time on a man forty-seven years of age, one year previous to date of this report.

I have thought that it might be of interest to the Society to note the results of these two operations performed at the same time upon this man, one year having elapsed since they were done. I do not show him at this time as an example of accomplished radical cure, at any rate of the hernia; although I think we may be fairly certain that he will have no return of his hydrocele.

The patient has been the subject of double inguinal hernia for about ten years, and of hydrocele of the left side for about six years. The hernia on the *right* side is still easily controlled by a truss, while that on the *left* side has been very troublesome to manage with a truss, for a year previous to the time of the operation. The hydrocele on the same side as this hernia, had failed of cure by repeated tapplings, and the patient was advised by me to have the attempt at radical cure of both hernia and hydrocele on the left side, made at the same time.

Early in November, 1890, the hernial and hydrocele sacs were exposed by one long incision. The hydrocele sac was much thickened, while that of the hernia was very thin, except about its lower end, where it was found to be tightly adherent to the sac of the hydrocele. After separating these adhesions, the hydrocele sac was laid open anteriorly, and excised, being cut off as close to the testicle as possible. The hernial sac was empty (the gut being easily reducible, and the ring very wide), and, about the ring, was slightly adherent. It was separated entirely from about the inner surface of the ring, and then tied high up within the ring, and cut off close to the ligature. The skin on either side the ring was then inverted, as directed by Dr. McBurney, and sutured. The ring was, as has been said, very wide; its sides were approximated by three silk sutures; a plug of iodoform gauze was inserted into the space between the sides of the wound and an aseptic (sterilized) dressing applied externally. The sutures were removed at the end of sixteen days, in which interval the wound had partially filled with a mass of healthy granulation tissue. The patient remained in bed for six weeks, by the end of which time there remained but a superficial granulating area, which completely healed at the end of ten days more. The wound of the scrotum made for the purpose of excising the hydrocele sac was tightly sutured, and united by first intention. There was a good deal of shock immediately following the operations, but with that exception the patient had no untoward symptom whatever.

For two months after getting up the patient wore a firm inguinal pad, which he discarded at the end of that time. The ring was then seen to be occupied by a mass of connective tissue which at that time retained the gut above it perfectly. To-day, at the end of one year, he reported himself for examination. You will notice that there is not the slightest tendency to return of the hydrocele, and also that the same is true thus

far of the hernia. The ring is still occupied by a plug of connective tissue which bars entirely the introduction of the finger from below, and equally of any protrusion of the hernia from above. The case, therefore, is up to date wholly successful. I note, however, that while the connective tissue plug is at present sufficiently strong to retain the gut behind it, that it nevertheless is very much less dense than it was when I examined it about five months ago, and that it gives to the touch the impression that less force would be required now than then to displace it.

## A CASE OF DIVISION OF TENDONS AND NERVES AT THE WRIST.<sup>2</sup>

BY FRANCIS S. WATSON, M.D.

This man, who is about thirty-two years old, I wished to show in connection with Dr. Conant's cases, as another example of a similar condition.

One month ago, he drew a knife across the front of his left wrist, with suicidal intent, and with the result of dividing the following structures: The tendons of the flexor carpi radialis, palmaris longus, flexor sublimis digitorum, flexor proprius pollicis, flexor carpi ulnaris, and one of the tendons of the flexor profundus digitorum. Beside these tendons, the median and ulnar nerves and the ulnar artery were divided, and the wrist joint opened on the ulnar side of the arm. The incision was transverse, and extended entirely across the anterior surface of the wrist, on a line about one-half an inch above the junction of the carpal and metacarpal bones.

It was possible to draw into view from the palm, the severed ends of three of the tendons of the flexor sublimis and that of the palmaris longus, these as well as those of the flexor carpi ulnaris and radialis were sutured. It is, however, very doubtful whether the ends of the tendons of the sublimis were united to their proper mates, and it is certain that one tendon of the sublimis and one of the profundus, were not united at all. And it is also certain that neither median nor ulnar nerve were sutured, as it was impossible at the time to discover the distal ends of either without a more prolonged search than the condition of the patient (who had lost much blood previous to coming to the hospital) would allow with safety. The ulnar artery was tied at both ends, the outer wounds closed tight and a sterilized gauze dressing applied. The hand and forearm were placed on a splint with the fingers in a flexed position.

The wound united by first intention. At the end of two weeks, the patient had recovered sensation in the region of distribution of the median nerve; and at the end of three weeks in that of the ulnar, though to a less degree. He is, at this time, one month from the date of operation, able to partially flex all the fingers and the thumb, and his ability to do so, has rapidly increased during the last four days.

That which interested me in this case especially was the restoration of sensation to all the fingers and the thumb, when we knew that the median and ulnar nerves had been severed and not reunited by suture (the suture of the nerves had been left until the last, and then was not done owing, as has been said, to the threatening condition of the patient, in part, and, in

<sup>1</sup>Read before the Surgical Section of the Suffolk District Medical Society, November 1, 1891.

<sup>2</sup>Read before the Surgical Section of the Suffolk District Medical Society, November 1, 1891.

part through failure to readily find the distal ends); and also the restoration of function of the divided tendons, in spite of the failure to suture two of them, and also when the tendons that were sutured may not have been properly matched.

I would also like to say how much more readily the tendon sutures were applied by employing the device that Dr. Mixer showed to us a year or so ago, of drawing out the upper end of the tendon to be sutured, as far as it is desired, and then maintaining it in position by transfixing the tendon and its sheath at the same point above its cut end, the tendon then cannot retract, and no strain comes upon the sutures until they are all applied and the needle withdrawn.

### CASE OF DOUBLE OVARIOTOMY.<sup>1</sup>

BY MALCOLM STOREY, M.D., BOSTON.

WHILE I regret that the case which I have the pleasure of reporting does not deviate more from the normal, it may still have some points of interest.

The patient, Mary A., was very kindly referred to me by Dr. H. H. A. Beach. She was born in Massachusetts, was eighteen years of age, and was a somewhat undeveloped and anæmic blond, tending a little towards the scrofulous type. She was about five feet in height, and weighed after operation ninety-eight pounds. As possibly having some slight bearing upon the vexed question of a hereditary disposition to abnormal growths, it may be mentioned that an uncle on the maternal side died of cancer. That her father had some years ago a cancer of the lip, removed by Dr. Beach at the Massachusetts General Hospital, and that a somewhat strikingly large number of other members of her family have been troubled by the smaller cystic growths of one kind and another.

She began to menstruate at twelve and one-half, the first catamenia being attended by much pain, backache, etc., although since that time menstruation has been regular, of normal amount, and not attended with discomfort. While never having suffered from any definite disease, ever since puberty she has been more or less of a chronic invalid with obscure symptoms, headache, dyspeptic disturbances, lassitude, etc., but was able to keep about until eighteen months ago, when she first noticed abdominal enlargement. At that time her physician, Dr. L. H. Luce, of West Tisbury, found well-marked enlargement of whole abdomen, fluctuation distinct in upper abdomen, gradually diminishing towards flanks and pubes, and uniform dullness over abdomen except a narrow space extending the entire length of hypochondriac and left iliac regions. Physical signs were not altered by position. "Internal examination was unsatisfactory but showed a large, fluctuating tumor pressing down anterior to the uterus." Having diagnosed the case correctly, Dr. Luce decided in view of her run-down condition, to wait a few months before advising an operation, and it is largely due to his efforts towards building her up, that her excellent recovery is to be credited.

In the last few months catamenia have been regular, their last appearance being ten days before operation. Her bowels had been regular, but defecation was often attended by great pain, which ceased with the move-

ment. She has also had occasional attacks of quite severe dysuria.

On examining the patient the heart and lungs were found to be in good condition. The urine showed nothing abnormal in bladder or kidneys. Examination of the abdomen gave practically the results observed by her attending physician eighteen months previously, except that the tympany in the flanks had almost disappeared.

Measurements were as follows: Abdomen at level of anterior superior spine, thirty-three and one-half inches; at umbilicus, thirty-three inches; at epigastrium, thirty and one-half inches.

Through the thin abdominal walls the tumor could be palpated with ease. It apparently was uniform in outline, and the consistency suggested contents of a colloid nature, although this was afterwards found to be a mistake. Owing to difficulties in the way of a vaginal examination, no diagnosis as to which ovary was affected could be hazarded.

I operated September 22d, kindly assisted by Dr. C. P. Strong. The patient's abdomen was prepared as follows: After being washed and shaved, a poultice of green soap was applied for twelve hours. Two hours before the operation this was changed for one of bichloride, the soap being carefully removed with hot water. Immediately before the operation she was scrubbed with bichloride 1-1000, and then with a mixture of equal parts of ether and turpentine. The instruments were sterilized, and dry sterilized cheesecloth was used for sponges.

The incision, a trifle less than two inches long, was made in the median line, without paying any especial attention to the linea alba. On entering the peritoneal cavity, the cyst wall presented, and on puncturing it with a large trocar, fifteen pounds of thin, dirty, straw-colored fluid was evacuated. The cyst was then found to be one of the left ovary, and there being no adhesions, was easily withdrawn through the opening. The pedicle, which was some two inches long and the thickness of a small finger, was clamped, cauterized, and tied with strong silk in the customary manner, and dropped inside.

The right ovary was found to be in a state of cystic degeneration, being enlarged to the size of a small lemon, and its surface studded with small cysts, and was accordingly also removed, the pedicle being treated in the same way. The abdominal wound was closed with silkworm gut, all the layers being included in each suture. The wound was dusted with aristol and a dressing of sublimate cotton applied.

The patient made an uninterrupted recovery. Her temperature rose to 100° on the evening of the third day, but promptly sank on her bowels being moved by a Sedlitz powder. Forty-eight hours after the operation catamenia came on again, and she continued to flow slightly for four days. After flowing for some twelve hours, being perfectly comfortable meanwhile, she suddenly discharged from the uterus some six ounces of offensively acid sour-smelling fluid, only slightly tinged with blood. Before and after this she had the ordinary catamenial flow. She had a similar discharge, less in amount, twelve hours later. Stitches were removed on the eighth day, and patient sent home on the twenty-sixth.

SUBSCRIPTIONS are being made in Vienna to place a bust of Carl Braun in the arcade of the university.

## New Instruments.

### A NEW METHOD OF CUTTING AND APPLYING SKIN GRAFTS IN THIERSCH'S OPERATION.

BY S. J. MIXTER, M.D.,  
Surgeon Corney Hospital; Surgeon to Out-Patients, Massachusetts  
General Hospital.

THE method of skin grafting as described by Thiersch is so well known and of such recognized value, that a description of its great possibilities, and the accepted details of the operation, need no new description. I wish only to call attention to two practical points that I think are new and which make the operation much more simple and accurate.

With practice and care thin strips of the skin may be taken from the thigh by the ordinary amputating knife. As a rule, such strips are ragged at the edges, and much of the graft is wasted, as the surface to be repaired must be entirely covered.

I have had made by Codman & Shurtleff, (Boston), the instrument here figured. It consists of a fenestrated, curved plate, of which Fig. 1 represents the under surface and Fig. 2 the cross-section. This has sharp needle points as shown, which serve to keep it in place on the skin of the thigh, which, being stretched before the plate is applied, is kept so while the graft is being cut. This plate being applied to the thigh, the roller (Fig. 3) is pressed firmly down upon it, thus flattening the skin between the thin edges of the plate, and the knife (Fig. 4) being carried at a suitable distance behind the roller, cuts a graft, thin and of uniform thickness. The knife should be used like a saw, with short, sharp strokes. Care must be taken that the knife blade is carried as nearly parallel

with the plate as possible, otherwise the edge is turned or nicked and the plate damaged.

The plate should be made of *hardened steel*, not brass, otherwise it becomes rough and the knife is spoiled every time it is used. The blade of the knife should be very sharp, thin and well tempered. In cutting the graft let the knife pass under it, leaving it on the surface from which it was taken.

The method of applying the graft so cut is the second point where I have a suggestion to offer. A few thicknesses of soft tissue paper (toilet paper is as good as any), properly sterilized and wet with warm salt solution is laid on the graft, and the paper and graft lifted together. The edges of the graft may be straightened out with a few strokes of a probe and applied in the proper place, skin down. The paper is then removed, leaving the graft in place with no curled edges. Should the graft be too long for the place where it is to go, the paper and adherent skin may be cut accordingly. Some practice is necessary before the instrument can be properly used. It will not "work itself."

## Medical Progress.

### RECENT PROGRESS IN ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D.

(Concluded from No. 26, page 682.)

#### GENU VALGUM.<sup>17</sup>

THE biennial statistics of the Racheit Institution at Milan, directed by Panaccheri, show 662 cases of genu valgum. The genu valgum double is much more frequent in children than unilateral in the first years of life. It is treated by apparatus, wood or steel on young children, if the deformity is not very pronounced. Forcible correction was made three hundred and eighty-one times in two hundred and seventeen patients. The method of Tillaux was employed, and there was never any articular reaction or tearing of the internal tissue. In six cases a relapse was noted, and in six a paralysis of the external popliteal

nerve, attributed by the writer to a compression of the apparatus. In cases eighteen years old it was corrected by osteotomy. Sixteen osteotomies have been done in ten cases. All have been followed by cure.

#### CURVED OSTEOTOMY IN ANCHYLOSIS OF THE KNEE.<sup>18</sup>

The writer reports a case of osteotomy of the femur just above the condyle, in a case of long-continued ankylosis at the knee-joint. Transverse incision was made; the tibia was separated, and, by means of a chisel, the femur divided transversely with a somewhat curved section just above the line of articulation. The section was made so near to the point of articulation

<sup>17</sup> Achille Zuffi: *Archivio di Ortopedia*, 1890, 1, 5.

<sup>18</sup> Kummer: *Revue d'Orthopédie*, Nov. 1, 1890.

tion that on straightening the limb subluxation was entirely corrected. Dissection was made in a curve corresponding to the normal line of the condyles. The case was reported to be thoroughly successful.

#### ARTHRECTOMY IN TUBERCULAR AFFECTIONS OF THE KNEE.<sup>19</sup>

The article is based upon seven cases observed by the writer. The conclusions are that arthrectomy is an operation without danger if done with rigorous antiseptics. Carefully done and carefully drained, it is suitable to certain cases of tumor albus; cases of tubercular synovitis, when the bones are not attached, children as well as adults. In children there are always present epiphyseal foci, and osteo-arthrectomy would be done in preference, avoiding the shortening which resection gives. In the cases of osseous lesion in adults, resection is better. Ankylosis is to be aimed at in arthrectomy, and in children an appliance is needed after the operation, for some time, not in adults. Compared with the resection, arthrectomy gives the same therapeutic result: it has for its advantage its simplicity, the amount of treatment and a better functional result.

#### RUPTURE OF THE QUADRICEPS TENDON OF THE LEG ABOVE THE PATELLA.<sup>20</sup>

He reports a case of this accident in a man of sixty-seven, where the tendon was sutured. In the case reported there was a great deal of suppurative, but the result was satisfactory; recovery occurred in a month and was aided by massage. Marc See, Monod, Kirmisson believes that a cure can be made without surgical intervention, and that the effusion into the knee disappears rapidly under the compression.

#### DISLOCATION OF PATELLA.

A method of treating a persistent case of slipping patella is reported by Mr. Bilton Pollard.<sup>21</sup> The case was an obstinate one, and had been previously operated upon by Macewen's operation, for the existing genu valgum, which was present, and supposed to be the cause of the trouble, but without relief. The operation performed by Mr. Pollard consisted of chiselling away a part of the trochlear surface of the femur, sufficient to make a deep groove, in which the patella could slide. It was found that the natural groove in this case was remarkably small, and provided no distinct resting place. A portion of the inner part of the capsule was also excised, and thus this part of the knee strengthened. The case did well, and in four months there had been no return of the trouble, although a slight grating could be felt on flexion and extension.

#### INTERNAL DERANGEMENT OF THE KNEE.

Mr. Noble Smith<sup>22</sup> advocates thorough trial of Hey's method of reduction by manipulation, repeated frequently, and cites cases in which this has succeeded in preventing relapse. He claims that the cartilage has been changed in form by the pressure in the unnatural position, and tends to work its way out unless kept in place sufficiently long to regain its shape. His method is to repeat the manipulation daily for a few days, then once every two or three days for a fortnight or more. He reports no relapses since pursuing this method.

#### BENDING OF THE NECK OF THE FEMUR.<sup>23</sup>

The writer describes several cases of this deformity, and gives specimens indicating the curvature. The literature is also carefully investigated. A case is reported which had been operated upon successfully by Hoffa, and the specimen indicates the amount of curvature at the neck, indicating that this rachitic deformity, which has not been hitherto regarded of importance, is, in certain cases, of interest, and demanding surgical treatment.

#### OPERATIVE TREATMENT OF IRREDUCIBLE DISLOCATIONS OF THE HIP-JOINT.<sup>24</sup>

The irreducibility of these luxations is due to the interference of the capsule or the muscles. The capsule can by its intact portion interfere with traction; the head button-hole through the capsule leaving a small opening; or one of the flaps of the capsule intervene and interfere with reduction. The muscles can oppose by being button-holed by the head, or the capsule may be interposed between the head and the cavity. In recent dislocations, if the irreducibility is certain, the surgeon can use arthrectomy and remove the ligamentous adhesion. If the luxation is old, one can try forcible movement, but it is necessary to use it with care. In dislocation a year old no manipulation is likely to be successful, and under those circumstances operative procedure is advisable. Resection to the joint should be done by an anterior incision. The ligamentous muscular obstacles should be divided, the cotyloid cavity enlarged, and the resection tried. If this is not possible, excision of the head can be done, enlarging the incision if necessary. This author reports seventeen cases; one a case of a child twelve years old, with a dislocation of three years' duration, which was cured by arthrotomy.

#### OPERATIVE TREATMENT FOR OLD LUXATIONS OF THE HIP.<sup>25</sup>

These writers mention a case of operative treatment of old ischiatic luxation of the hip-joint so severe that walking was impossible without crutches, and which they were unable to reduce. The operation was as follows: The femoral head was exposed by a posterior incision over the projecting head. The capsule was freed as it was adherent to the head, and the cotyloid cavity was enlarged with the gouge and mallet and the socket of the femoral neck was placed into the acetabulum. Healing was rapid, and recovery was made with some motion at the joint. The result is claimed to be much better than of cure by resection; only the head being removed.

#### OPERATIVE TREATMENT IN CONGENITAL DISLOCATION OF THE HIP.<sup>26</sup>

In a most excellent article on the subject the writer refers to the different procedures which have been introduced in the treatment by operation in that deformity. In regard to the pathology, he states that there are different articular lesions found, according to the age of the patient. In new-born children little alterations are found in coxo-femoral articulation. The cotyloid cavity is never wanting. It is not as deep as normal, and the normal curve of the posterior portion is wanting. Sometimes it is filled with connective tis-

<sup>26</sup> *Revue de Chirurgie*, Paris, Dec. 1, 1890.

sue or with fatty tissue. The head of the femur is not modified in general. The capsule and the round ligament are always intact, and in some cases they are only a little thin or elongated. The muscles are shorter and less developed, according to Verneuil. As the child grows older, and begins to walk, alterations take place. The cotyloid cavity does not grow as quickly as the rest of the bone, and the connective tissues increase and fill the cavities. Sometimes exostoses develop in the bottom of the cavity. The head of the femur elongates itself, or it sometimes flattens as if depressed, and sometimes presents a projection. It is often bent and applied to the body of the femur, making the neck incompletely developed. The capsule is solid and resistant; thus giving to the head an abnormal play. The round ligament is generally preserved, sometimes flattened and delicate, sometimes solid and thick. The muscles are retracted; at least those which are near the pelvis; not only those going from the great trochanter to the pelvis, but also those which pass around the articulation.

In the adult the changes are more marked; the head of the femur is raised, and the capsule remains intact, forming a very solid sac. The cotyloid cavity generally takes a triangular appearance, with one of the angles above and behind. Sometimes it is found completely filled, and in one observation exostoses in its place. Muscles are frequently modified. These observations which have been taken from autopsy are confirmed by observations by the writer on cases that have been operated on; and he claims that there is always a retraction of the soft parts around the affected hip.

The orthopedic treatment, the writer claims, has not taken into account this muscular retraction, and the cases of Pravaz, which were considered to be cured by Malgaigne, who proved that the cure was not permanent. The case of Buckminster Brown required a treatment by confinement to bed for a year and a half. Volkmann reported some cases which were satisfactorily treated by extension, but these cases were not permanently improved. The same is true of the treatment by silicate bandage, and appliances have not been of great value.

Operative treatment was first proposed by Guérin. It consisted of subcutaneous tenotomy. Bouvier, Brodhurst and others have attempted to use this method, but without marked success. Mayer tried osteotomy. Hunter advised resection of the head of the femur.

But, in brief, it may be said that the result obtained by resection has not been satisfactory, although the method has been tried by a number of surgeons, Italian, German, French and English. Hoffa collects 27 cases of resection, and shows us the following results: three good results, five average, and eight bad, without a single case of cure. He claims that the difficulty in correcting the reduction is due to the retraction of the soft part. He reports a number of cases which he operated upon by a method of his own; which consists of a straight incision, with a complete separation of all the muscular insertions on the great trochanter, and a complete ring of the capsule around the head of the femur. The place of the cotyloid cavity is then found, and is enlarged. The head is placed into this cavity in the same manner that a dislocation would be reduced, and the operation is concluded.

The results which he has obtained in these cases have been in every way satisfactory, with re-establish-

ment of movement in all cases, and cure. Kaci and Redard speak of the treatment of congenital dislocation of the hip by means of manipulations, which consist of flexion of the thigh, abduction, rotation, and extension. These exercises are to be carried on daily for some time, and in young children they report an improvement in the position of the head of the femur; this improvement to be maintained by a fixed dressing of plaster-of-Paris.<sup>57</sup>

Schüssler<sup>58</sup> prefers the resection of the hip in certain cases to Hoffa's operation, and reports a case with excellent results, not only in regard to the shape of the limb, but as to the functions, perfect motion having been established. The operation consisted of removing only the head of the femur, and a corner of the anterior portion of the neck, with the making of a depression for a cotyloid cavity. The method of Hoffa is not suitable for all cases. It supposes normal anatomical conditions, and these are not always found even in infancy. The patient of Schüssler was a girl fourteen years old, and there was a deformity in the head of the femur, which was altered in shape. Deschamps, in the *Gazette de Liège*, March 13, 1890, p. 280, reports a successful case of resection in a girl fourteen years of age, with apparent successful result.

William Adams<sup>59</sup> has treated six cases of congenital dislocation of the hip, two being double and four single, according to the method of Dr. Buckminster Brown, in three of the cases the right hip and in one the left. In two of these cases the treatment was carried out for two years. The result obtained is most satisfactory, for a careful measurement does not allow any shortening of an eighth or a quarter of an inch, and in one case it was impossible to find any difference in length of the limbs. The ilio-femoral triangle of the affected side corresponds closely to that on the sound side, in such a way that the head of the femur is maintained almost entirely in natural position, and there is no tendency to a spontaneous dislocation, either with or without movements. The patient still wears an apparatus as a means of protection.

#### WIRING OF THE VERTEBRÆ AS A MEANS OF IMMOBILIZATION IN FRACTURE AND POTT'S DISEASE.<sup>60</sup>

This operation has been done by Dr. B. E. Hadra for dislocation of the sixth cervical vertebra, and with such results that he claims it may be used as a means of immobilization in Pott's disease. In his operation, the ligamentum nuchæ and interspinous ligaments were severed transversely, and the wire passed several times, in the figure-of-8, around the spinous processes of the sixth and seventh cervical vertebra. The immobilization thus obtained was satisfactory, and although the case was of some duration, the symptoms were somewhat relieved. He considered, however, that section of the ligaments, as performed, interfered with the rapid healing, and suggests that only the muscular attachments be divided, and the loop passed over the processes by means of a curved needle. In this way the operation is comparatively bloodless, and can easily be performed. In wiring the transverse processes, the operation is more difficult, as the muscles must be more extensively divided and drawn aside. To avoid the nerves, he considers it better to first surround one process, then carry the thread to the next one, and

again tie it here by a loop, so as to have only one wire in the interspace.

#### LATERAL DEVIATION OF THE SPINE AS A DIAGNOSTIC SYMPTOM IN POTT'S DISEASE.

This subject has been carefully considered by Dr. R. W. Lovett.<sup>81</sup> Attention is called to the prevalence of this condition, particularly in the early stages, and its importance as a diagnostic sign. It is regarded by him as generally of muscular reflex action, analogous to that seen in joint disease. It differs from the distortion in true scoliosis, as the curve is more sinuous, displacing the shoulders laterally, and in the absence of marked rotation, which is more apt to be on the side of the concavity than on the side of the convexity. The amount of deviation was found to vary from two or three to eight degrees from the perpendicular, and this latter was extreme and not usual. In slight degrees it may often be more easily recognized by viewing the patient from before. The difficulty of properly treating these cases is referred to, and support by means of the plaster jacket is regarded as the most satisfactory.

#### HUMAN CARRIAGE IN REFERENCE TO CURVATURE OF THE SPINE.<sup>82</sup>

Staffel describes the three following types: The rounding back, with a kyphosis, dorso-lumbar, apparent or real, indicates, according to the writer, a temperament without energy. The cause of this attitude is a fault of will rather than of muscular feebleness. These cases represent the most favorable ones for treatment, and a corset well made is sufficient for them. The second class, is the flat back with a lumbar kyphosis (relative or absolute), lordosis of the dorsal region (relative or absolute), with the vertebral column retaining the character that it had in infancy. This form brings with it a tendency to lateral curvature, rickets and a defect of muscular energy, and also a tendency to the first variety of scoliosis. The hollow back is the third variety, which comes from a narrow pelvis surmounted by a spinal column with an exaggerated lumbar curve; the dorsal region is flat.

Besides these types there are other mixed forms; as back of tailors, which consists in an exaggeration of the normal curve, the back being both round-shouldered and hollow in the lumbar region. All these forms we can find with scoliosis, though the latter is more common in the round and flat backs. The lateral posterior curves are generally considered as secondary to scoliosis, but it is supposed that in a certain number of cases it may precede scoliotic deformity. In severe cases of scoliosis there is no trace of a normal lumbar lordosis, which would indicate that the lordosis was wanting before the beginning of the affection, which is developed especially with flat backs. The seated position is particularly dangerous for the development of scoliosis; and Staffel recommends treatment to diminish as much as possible the sitting position, and to increase the normal curve in the lumbar region by the employment of a suitable seat.

#### OSTEOMYELITIS OF THE VERTEBRAL COLUMN.<sup>83</sup>

Observations of this disease are not numerous. It is analogous to the osteomyelitis which is seen in the

long bones. It can attack the bodies of the vertebrae and the vertebral arches. It may be acute or chronic.

#### SCIATIC SCLIOSIS.<sup>84</sup>

The author mentions that he first observed two cases in 1878, at Liege. In 1886 Alberg reported three cases of this affection, and Nicoladoni has published several others, showing the relation between scoliosis and sciatic neuralgia. In 1888 Babinski reported five cases in Charcot's clinics, and claimed the first description of the affection, but others have also claimed the first investigation. Gutenberg has had the opportunity to watch nine cases. Men are more frequently attacked than women. The symptoms are always the same, and appear in patients who have suffered from sciatica for a long time. The twisting of the vertebral column comes on gradually or suddenly. As Nicoladoni has observed, there is a tender point always to be felt between the last lumbar vertebrae and the posterior iliac spine. It may be added as a matter of diagnosis, that this variety of scoliosis disappears completely when the patient is suspended. The pathology of the affection is not definitely known. The writer considered that the affection is due to a muscular spasm, and for treatment he had found benefit from massage and electricity. In one case long-continued baths were an advantage; and in one case nerve-stretching of the sciatic nerve was tried with benefit.

Lamy, in the *Review of Orthopedic Surgery*, contributes an article on scoliosis in sciatica, and mentions the variety of attitudes.<sup>85</sup> He speaks of different attitudes, with a certain amount of variation in curve.

Levy<sup>86</sup> writes of the fact of the physiology of lateral curvature, and states that the bad school-sitting in the third position in writing, and in their fitting schools, may be the occasional cause of lateral curvature, but it is not the primary cause; if that were the case, boys would be as often attacked as girls. The true cause is rather in the physical education of young girls. The modification in the education of girls should consist in approaching as far as possible to that which is given to boys. The difference is the method of educating both sexes, especially in that the young girls remain in a seated position a longer portion of the day than boys; and the author advises that the hours of study should be interrupted by gymnastic exercises, singing-lessons, dancing-lessons. He thinks that it is better not to attempt to burden girls with unnecessary scientific notions, but to develop their bodies.

#### CAUSES OF ROTATION OF THE VERTEBRÆ IN SCOLIOSIS.<sup>87</sup>

Mr. Little gives the results of experiments on the cadaver, in attempting to produce rotation by superincumbent weight. He found first, that in the living subject, rotation was produced by lateral flexion in the upright position, but that this did not occur in the prone. In the first experiments the cadaver was laid on the back, and forcible flexion made; but no rotation was produced. The anterior common ligament was divided, and later the intervertebral discs and posterior common ligament; but no rotation was produced. Under superincumbent weight a lateral curve resulted, but no rotation, and this also after the ligaments were

<sup>87</sup> Lane: 1894, vol. I, p. 191.

divided as before, and the tissues between the transverse processes on one side were severed.

His inference is that it is not an accompaniment of normal flexion, but that it is due to the unequal tension of the muscles. The erector spinae, longissimus dorsi, sacrolumbalis, multifidus spinae, rotatores spinae, have insertion to one side of the spine. If acting together, there is no tendency to rotation; but when acting alone as a lateral flexion, a tendency to rotation is developed.

#### MUSCULAR STRENGTH OF THE BACK IN GROWING GIRLS.<sup>55</sup>

Dr. C. L. Scudder has grouped the results from a large number of observations on the strength of growing girls. These were taken of school children, by means of a chair with a movable back, and the record taken by a self-registering dynamometer. At the same time the height, weight and age were taken; and thus a valuable table is given for comparison of the cases of lateral curvature. The element of muscular weakness is regarded by the writer as an important factor, and thus the treatment should be adapted more intelligently to individual cases.

#### TORSION OF THE SPINE IN SCOLIOSIS.<sup>56</sup>

This is to be regarded as a true osseous torsion, according to Lorenz, Fischer, Albert, Mikulicz, Kocher and Nicoladoni, of Berlin, have regarded it, not as a true torsion, but as an optic illusion resulting from the lack of symmetry of the vertebral column. To demonstrate this, Nicoladoni removed a cortical layer of a vertebral body, and he claims to have proved that there is not a torsion of the vertebrae reaching to the summit of the curve, but only of the vertebrae of transition. This torsion is in correspondence with the anterior ligament. The veins of the side are pushed to the side of the convexity. Laterally the fascia of the anterior ligament is large, thin towards the side of the convexity, and thick and folded on itself on the side of the concavity. This may be regarded as the consequence of the more rapid growth of the bone on the side of the convexity, and the intimate union of the periosteum with the ligamental fibres. The cause of the asymmetry of the scoliatic column is, according to Nicoladoni due to the modifications in growth, produced by difference of superincumbent weight. In support of his view he cites the modifications of the form and of position which he has been able to find upon the epiphyseal cartilages of many young subjects, among these an infant of a year attacked with scoliosis. In this case the ossification was much more advanced on the convex side, while on the concave side the ossification in a large part of the epiphyseal cartilage had not yet begun.

#### TREATMENT OF SCOLIOSIS.<sup>57</sup>

The writer divides the distortion into three phases or periods: first, the curvature before there is any rotation; second, the curvature with rotation; and third, a curvature with an osseous change of the vertebrae. In the first stage it is impossible to form a diagnosis without taking off the shoes; for, as a rule, in children and adolescents, flat-foot and alteration of the pelvis, determine to a certain degree the deformity. But when these modifications have been produced, any

increase of the heel will exaggerate the degree of scoliosis in such a way that a spine slightly curved can acquire a very considerable curvature with raised heels, a curvature which will increase in proportion to the height of the heels. This can be demonstrated by examination.

#### AN ARRANGEMENT FOR CORRECTION OF DEFORMITY OF THE THORAX IN SCOLIOSIS.<sup>58</sup>

Hoffa describes an arrangement which will exert pressure upon the projecting rib in the thorax, and will correct the deformity which is present. This apparatus can be used in exercise; it can also be used for correction and the application of a plaster jacket. The arrangement is more directly for the correction of rotation, not for the protection of the ribs. The arrangement consists of a single bar, which is fastened between two uprights. The bar is bent so as to encircle the thorax behind, and an inch steel piece passes in front. From this bar, rods with screw-threads working at right angles are fixed so that they can be adjusted laterally to press upon any position. These rods are furnished with a plate so as to exert pressure where applied. In this way a direct pressure can be placed upon the thorax, the pelvis being fastened by means of a strap.

#### TREATMENT OF LATERAL CURVATURE.<sup>59</sup>

Lorenz reports a method of treatment for correction of lateral curvature by the application of suspension and also lateral suspension, which consists of straps which are wound about the patient's trunk spirally, so as to exert a pull in the direction of torsion, and also in the direction of the projection of the ribs. For the application of these straps the reader must be referred to the article itself, as these vary to a certain extent according to the curve. But the theory adopted by the writer is that distortion of this character can, in certain cases, be entirely corrected by means of lateral pressure applied by these straps, the superincumbent weight being removed by suspension. The application of these straps may be used as a daily exercise. It can also be used for a complete correction of the patient, and for the application of a plaster jacket, or for the manufacture of a corset. It has been the experience of Lorenz that under these exercises improvement and correction take place.

## Reports of Societies.

### MASSACHUSETTS MEDICAL SOCIETY. SUFFOLK DISTRICT. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

ALBERT N. BLODGETT, M.D., SECRETARY.

REGULAR Meeting, Wednesday, November 18, 1891,  
Dr. E. G. CUTLER in the chair.

#### REPORT ON EMERGENCY HOSPITAL.

The first business was a communication from the committee appointed to consider and report to the Society the need of an emergency hospital. That committee was not prepared to make a final report at this meeting, and asked for further time, which was granted.

## REPORT OF COMMITTEE UPON THE CONDITION OF THE STREETS OF BOSTON.

DR. V. Y. BOWDITCH, for the Committee on the Condition of the Streets of Boston, stated that the committee had occupied itself in interviewing, at various times through the year, both Mayor Hart and Mayor Matthews, Governor Russell, the Police Commissioners and the Superintendent of Sanitary Police. Without arrogating too much to the medical men, Dr. Bowditch believed that the action of the Suffolk District Medical Society last year, had been of great service in procuring a cleaner condition of the streets. Immediately following their action, the press had strenuously supported them and urged the necessity of greater cleanliness; and in the following autumn both candidates for the mayoralty had made the subject of special import in their messages and although there is still much room for improvement, no one can deny that the city in the business portions, at least, is much cleaner than before, the reforms being largely due to Mr. Carter, the present Superintendent of Streets.

In all their interviews a marked cordiality has been shown to the efforts of the Committee, except by the Police Commissioners, who for some reason or other show a decided indifference to enforcing laws on the statute books for the prevention of throwing refuse into the streets by shopkeepers and others. The watering of the streets has greatly improved in the past year, doubtless due to the energetic action of Dr. H. J. Barnes, who, independently of the committee, had sent several letters to the newspapers relative to this subject. Dr. Bowditch hoped that Dr. Barnes would be added to the committee, and stated that it was their intention to pursue the same course as heretofore by interviews with various officials relative to still greater improvement in the condition of the city.

DR. J. C. WHITE moved the addition of Dr. Barnes to the committee, which was seconded by Dr. Knight; and he was unanimously elected.

DR. WARREN: I think the work the Society has done has had its effect, and that the condition of our streets, while far from the desired point, has been much improved. This is one of the great improvements, it seems to me, this country has got to make, not only for the comfort but for the sanitary advantage of the citizens. We expend enormous sums of money for parks, for luxurious hotels, for means of conveyance; we are making great improvement in comforts and conveniences in the way of living, and yet we are almost Chinese in the standard which we set for street engineering in this country. I do not speak of Boston so much as of other cities. I think Boston compares favorably with them, but there is still a great deal to be done. In fact, the science of road engineering is in its infancy in this country; and we want to stir continually, in order, not only to gain what is now proposed, but to spur on the authorities to educate themselves up to a much higher standard of work than they have ever aspired to before.

DR. BARNES: I desire to say something on this subject, for it seems to me we owe to the present administration, regardless of our political affiliations, recognition of the wonderful changes it has effected in the appearance of our streets, particularly when we recall the reported interview of our committee with the municipal authorities of a former administration, where every obstacle was placed in the path of this much-needed reform.

In reviewing the report of that interview, it would seem as if all efforts had been exhausted in an endeavor to find how *not* to do the work. For years filth was allowed to accumulate between the double lines of horse-car tracks, owing to a controversy between the street railroads and the city authorities. I chanced to pass through Boylston Street last spring at the time of its removal. Piles amounting to a good horse-load, as frequent as space would permit, were scraped up for loading; and I was much surprised to observe a good stone pavement underneath, which had been hidden for years. The cross-walks are now swept; the piles of rubbish collecting in the lee of the fences of bridges and curbstones have generally been removed. Prior to this year, I often was obliged to take up from two to five bushel baskets of road detritus gathered during windy days in front of my residence; nothing of this character has annoyed me during the past season; neither have I observed the offensive odors of the streets so common a year ago.

It seems to me we can now compare our condition with that of some of the better municipalities, and not be obliged to go as far as Constantinople or even New York to find a parallel.

An appropriation of \$150,000 last spring, three times the usual amount, was placed at the disposal of the Superintendent of Streets, for sprinkling, and the clouds of dust of former years, resembling a simoon in Sahara, have not been our unhappy experience. This branch of the municipal service has not as yet been placed on a good business basis, and excessive sprinkling has been noticed much of the time; but I am informed plans are being matured to systematize the work.

With the experience gained during the past year we may reasonably expect better service next year, and the establishment of an equitable method of payment. The committee of the city council having this subject under consideration is composed of gentlemen in whom we may repose confidence.

While commending the present administration for what it has accomplished, we may congratulate ourselves for the influence we have exerted, for in this hall and by you, these reforms were inaugurated, and by your committee brought to the attention of the municipal authorities. And when we remember the successful labor of members of our profession, which resulted in the building of the intercepting sewerage system; the reform in milk inspection, which chiefly through us has been secured; the elimination of sources of pollution of our water-supply; and the excavation of the storage basins of the Sudbury River, which, by the way, has practically revolutionized the practice of engineers in constructive work of this character, — we have much to encourage us in persistent effort to improve the sanitary condition of our city.

Dr. Barnes presented the following motion:

*Resolved:* That the members of the Suffolk District Medical Society, Section for Hygiene, etc., desire to express their gratification at the improved condition of the streets of Boston, and hope the effort for improvement will be continued; that we may ultimately be able to compare their condition with the best examples in other municipalities.

*Resolved:* That this motion be printed in the report of this meeting.

The motion was unanimously adopted.

DR. H. F. VICKERY read a paper on

UNSUSPECTED HEART-DISEASE.<sup>1</sup>

DR. E. N. WHITTIER: I think we are under great obligation to Dr. Vickery for the manner in which he has brought to our attention a subject of vital importance. The physician's duty to his patient in this respect was dealt with somewhat late in the paper, but I think in a very considerate way. I have always taken the ground in dealing with my patients, that, if they could not give me under such circumstances as those of heart changes, the full assurance that they would do what I asked without asking me why I advised it, it was my duty to inform them why even at the expense of creating in their minds what in my judgment would be a warrantable degree of apprehension. I know of no greater evil in the community than that which exists in the practice of some physicians of turning loose their patients who have been for some considerable time the victims of unsuspected disease of the heart; for the unexpected in such cases is almost sure to happen. In proof of this I desire to cite a few cases from my own experience.

CASE I. A gentleman of sixty, of rather stout habit, living at some distance from the city, endeavored to transact business in the city, and was in consequence exposed to the contingencies of haste. This gentleman called upon me, and stated that he had been troubled of late with dyspepsia and some shortness of breath, on what he called proper and not unusual exertion. Examination showed that his condition was that of an advanced chronic interstitial myocarditis. There was no evidence at that time of any valvular lesion. I told him on no account was he to hasten to a train or upstairs, etc. He came to me several days later to make a confession and an admission. He had done what he had been warned not to do; had received his lesson, and he said he should in the future govern himself accordingly. He noticed a man in front of him hastening to catch the train. Somewhat stimulated by that he started on a quick walk and finally into a run, and got into the car in time to save his passage on that train. He sat down breathless. He noticed three seats in front of him the man who had hastened a little before him. His head had dropped, and he was dead. That was the confession and admission.

Three weeks ago a gentleman sixty-three years of age came into the office of the life insurance company where I am employed, having been brought there by an agent, stating that he was a man of large affairs and it was of very considerable importance to him as an agent to secure the risk. There was certainly nothing in the appearance of the gentleman to suggest the slightest objection or impediment to his having a policy placed upon his life. I took his pulse. It seemed to me a little quick. It was eighty. I have been in the habit of taking a man's pulse at the beginning and end of examination and comparing the two. He stood up after he had answered the questions in the application and then I placed my ear against his chest and immediately my hand to the wrist, because there seemed to be an accountable difference between the cardiac movements as heard and the radial pulse. There was a difference of forty ineffectual and incomplete ventricular contractions; the apex pulse was 120. This to the agent was a case of unsuspected heart disease; to the examiner not wholly unsuspected, but without the usual warrant for so concluding; for this gentleman had

told me he could go up three flights of stairs without disturbance, and for thirty-six years had not had a physician. I think Dr. Vickery is right in the statement that he made, and I wish it could be put more strongly, that the forms of heart-disease which are unsuspected, and undiscovered by some physicians, and without any apprehension on the part of the patient or his friends, are the changes which take place in the muscular structure of the heart and not in its valvular organization. For this condition it seems to me there is comparatively slight remedy. We have not that to depend upon which we have a right to depend upon in the larger percentage of organic disease of valvular origin. There can be no satisfactory benefit or improvement conferred upon the patient unless he is made to feel alive to the necessity of following to the very letter such directions as may be given. I do not agree with that man who would say, if he has a heart-disease, he does not wish to know it; nor do I agree with those friends who are unwilling to take the risk of alarming a patient by an opinion of an existing cardiac disorder or disease, admittedly of grave significance, when the opinion, if heeded, shall be conservative in its tendency and protecting in its influence; and when, unheeded, because suppressed, be so frequently the source of unavailing regrets in the unexpected and unprepared for result, sudden death from cardiac inefficiency.

DR. F. C. SHATTUCK: I merely desire to express my cordial agreement with everything the reader has said. While he was reading the last paragraph I called to mind a conversation which I had the other day with Dr. John T. Metcalfe, of New York, whom I regard as the most skillful physician I have ever known. The conversation was on this very subject. He told me of the case of a gentleman whom he went to see on Fifth Avenue, whose wife had sat at the window every afternoon for many years watching to see her husband come home from his business, not knowing whether he would come home alive or dead, and that because they had been informed that he had heart disease and was liable to sudden death. Dr. Metcalfe told the lady that her husband might outlive both of them. The next year he went to Europe, and is still alive.

DR. F. MINOT: I should like allude very briefly to two or three cases which are interesting in this connection. I have reported one of them already to this Society, in a paper on another subject. The patient was a private coachman, accustomed to a good deal of exposure to the weather and who did the usual amount of laborious work which a coachman does. He came under my care in the hospital, with pneumonia of moderate severity. On feeling his pulse I was struck with its hammer-like character, which is so diagnostic of aortic regurgitation, and which was increased when the arm was raised up. On examination of the heart the characteristic diastolic murmur was plainly audible. This patient had no rational symptom of heart-disease, and notwithstanding the regurgitation, his pneumonic symptoms were comparatively light although perfectly well marked; and he was convalescent in about seven days.

Another case is that of a gentleman who consulted me many years ago, and who knew that he had a heart-disease. He was a man of nervous temperament, rather hypochondriacal, and fidgety about the nature of his complaint. I found that he had no rational

<sup>1</sup> See page 692 of the Journal.

symptom whatever of cardiac disease, although there was a well-marked mitral regurgitation. I have watched the patient for ten years, and I think he is in as perfect health now, as when I first saw him.

The third case is that of a young woman whom I saw in Chelsea a few years ago, in consultation with the late Dr. D. D. Gunter. She was hemiplegic and had aphasia. I found that she had a very loud and harsh mitral regurgitant murmur. It was audible at some little distance from the patient, and was a source of considerable annoyance to her husband, by keeping him awake. In this case, I think, the hemiplegia was clearly traceable to the heart-disease, and it seems possible that if the patient had been under treatment at an earlier period, her life might have been preserved for some years longer. One very interesting thing about this case is that the hemiplegia complicated with aphasia was on the left side, but the patient was not left-handed. The patient recovered partly from the aphasia, but died shortly after from a fresh attack.

DR. F. I. KNIGHT: These cases of unsuspected valvular lesion are familiar to all of us who have to do with thoracic disease. I think that cases of myocarditis are suspected because they come to us on account of cardiac symptoms. These cases of unsuspected valvular lesion come under observation in two ways: first, in the life-insurance cases; and, secondly, we see them constantly in patients whom we have known to have had endocarditis. Of course, some of these lesions are such as are not likely ever to produce any serious effect; and certainly they go along, as a rule, until compensation fails, and when there is a failure in compensation, they make some complaint, but, as a rule, not until then.

Whether a patient should be informed of his condition or not, is, of course, often a serious question: but it seems to me that it is usually perfectly right and important to inform him of his condition in a proper manner. I must confess I have seen a good many cases where I thought it was done in a very brutal manner: where the patient has been told at the first interview that he has serious cardiac disease, and is liable to drop down any minute. But a patient can be informed that he has some affection of the heart with which he will probably go along many years with care. I have seen recently an illustration of that brutal way of putting things, which, however, was not a case of heart-disease. A gentleman, about thirty years of age, consulted his family physician, and was sent to another physician here for consultation, who wrote a letter announcing that he had serious tubercular disease both of the larynx and lungs, and that it was an utterly hopeless case, and the only thing to do was to make him comfortable for the few months left him to live. This gentleman was in what he himself considered to be a very good physical condition. He did not suspect that he had serious disease at all. He asked the family physician what the doctor in Boston had written about him. This gentleman takes the letter out of his pocket, and throws it over for him to read. He reads it, and comes up with it to me, and asks me what I think about it. Now it seems to me that that way of dealing with a patient, even if there is not much hope, is very brutal. That same method of dealing with patients I have seen several times in cardiac cases, where I think it did an immense amount of harm, where a more proper way of putting the thing would have done the patient good instead of injury.

DR. V. Y. BOWDITCH: I am glad to have the opportunity of emphasizing the remarks of Dr. Knight with reference to speaking to our patients in whom we have found symptoms of disease. I agree with Dr. Whittier that it is of a great deal of importance to let the patient know he must avoid certain things; but, on the other hand, I think we must use the greatest care not to alarm him too much. I have seen too much of that sort of thing in people who have been told that they had serious heart-disease. We cannot be too careful, moreover, about explaining to the patients the difference between functional and organic disease. There are certain gentlemen who examine young men with reference to their ability to go into athletics. Some of them are doubtless capable of judging whether a man has the nervous build to enable him to go into athletics to a great extent. There are a good many young fellows of rather a neurotic temperament whose hearts, when they take violent exercise, behave in a way that would be serious if not controlled. Cases have come to me where they have been told by some one that they had serious disease of the heart, and they have been made most unhappy thereby. On examination I could find not the slightest evidence of organic disease, but some nervous irregularity. I do not, of course, wish to be understood as saying that it is wrong to speak to a patient about heart-disease at all. On the contrary, I think we can wisely advise a patient, but it seems to me we must use the greatest care in the way we do it.

DR. A. N. BLODGETT: In regard to informing patients as to their condition under circumstances of cardiac disease, I have found invariably that a careful and considerate communication to them of the condition of the heart, which renders it necessary for them to be cautious in what they do, can be made without exciting unnecessary alarm. I make it a point to tell them there is very little which they cannot do as well as other people, but that they must do it more carefully. I caution them against hurrying for trains or going up stairs quickly, or in any other way calling upon the weakened heart for extraordinary or sudden increase of work. I assure them that otherwise they can do almost anything which other people do, and may confidently look forward to a comfortable and happy life. I have not observed any ill effects from communicating in this manner the serious nature of the disease to the patient.

DR. H. F. VICKERY: In the first place, I should agree most fully as to what has been said about the manner in which patients should be informed. My words were, "A sensible patient properly advised as to his physical limitations may be able to lead a long, happy and useful life, whereas unwarned he may soon collapse"; and that is what I firmly believe. I believe there might be exceptions to that. The patient, for instance, may not be a sensible patient. If you tell some patients the truth about anything, the cerebrum does not get the truth.

As for being afraid to speak about heart-disease to a patient because the lady object to that term, I do not know whether I quite agree with that as a reason, because I suppose the reason the lady now are so afraid of heart-disease is that doctors were fifty years ago; and I live in hopes that patients in time will begin to think that pain in the back does not mean Bright's disease, that a tumor is not necessarily a cancer, that heart-disease is not inconsistent with a happy and useful life,

I did not mean to bring up treatment; but the point I want to make, and I think all have agreed to that, is that unless you examine you are not in a position to tell even those you ought to, and you cannot direct the patients rightly, if they have this trouble, in such cases as do not present rational symptoms.

DR. MALCOLM STORER read a paper on

#### A SUCCESSFUL CASE OF DOUBLE OVARIOTOMY.<sup>2</sup>

DR. CUSHING: I do not know that the paper calls for anything but flattering comments. The description is accurate. I think it is rather rare nowadays, that we find simple tumors which can be removed through a small opening by puncture. They are, in my experience, rather rare and very gratifying to get. The return of hemorrhage from the uterus soon after operation is a very common, and as far as I know a very favorable symptom. It is one I always like to hear of. Whether it lessens the pelvic congestion, or for what reason, I do not know, but patients who have this hemorrhage, called metrorrhagia, go on well usually.

#### PATHOLOGICAL SPECIMENS.

DR. E. W. CUSHING: I have brought the following specimens, which I have removed within the last fortnight.

First, two ovarian cystomata. One is interesting as occurring in a woman sixty-nine years old, who had always been healthy until something less than a year ago, when she first noticed this growth, which increased rapidly. As you see, it is largely solid, and not all the fluid could be removed by the trocar; possibly, a gallon was thus evacuated. The broad pedicle was secured in three sections. Irrigation, drainage-tube, and an uneventful recovery.

The second specimen is from a patient sent by Dr. Jenkins, of Greenland, N. H. It is a papillomatous cyst. It is interesting from the fact that, about two weeks before the operation, the patient, in rising to leave a railway car, was thrown against the seat in front of her, and probably ruptured the cyst; she was seized with violent pains and symptoms of shock, but rallied, and was able to come to the city for operation. On opening the abdomen a large amount of free peritoneal fluid was found, and a great many adhesions. The fluid being evacuated, and the cyst enucleated, it was found that there was a multitude of minute papillomatous excrescences on the intestines, uterus and omentum; a considerable portion of the omentum was amputated, in order to remove the chief focus of the new growth. Irrigation and glass drainage. Convalescence uninterrupted. The future course of this case will be awaited with a great deal of interest, to see whether the minute papillomata, which are scattered over the abdominal organs will continue to grow or will wither. This is a question on which little is written or known. In some cases, certainly, papillomatous growths continue to occur, but these may be cases where the original disease had penetrated so far between the folds of the broad ligament that the whole of the new growth was not extirpated at the time of operation. On the other hand, there is no doubt that minute papillomatous growths on the abdominal viscera may be so encapsulated by an adhesive peritonitis that their progress is arrested. I had such a case more than a year ago, where, besides the ovarian tumor, which was removed, there were multitudes of little

growths, presumably due to a previous rupture of the sac; these little vegetations, however, were surrounded with adhesive peritoneal coverings, so that they were apparently not growing, and the patient is now quite well, more than a year after the operation. The two tumors here shown display very well the two chief varieties of ovarian tumor, namely, multilocular cyst (some parts of which form a practically solid growth), and the mono-cyst, lined with papillary vegetations.

I have next to show two specimens of cancerous uterine removed by vaginal hysterectomy: there should have been three, but the third, by some accident, was not brought here. There is nothing very peculiar about these specimens, but it is interesting to see how high the disease extends in the cervix, even where inspection before operation would make us think that the disease is quite limited. You will observe that the upper border of the carcinomatous nodule is in both cases above the level of the entrance of the uterine artery; to remove the disease by high amputation, it would therefore be necessary to separate the bladder in front, and to open Douglas's pouch behind, and to secure the uterine arteries on each side; when this has been done, it is a slight matter to remove the fundus also. Any other course involves the risk of leaving a portion of the disease behind, the presence of which cannot be detected before or during the operation. All these patients recovered without accident. I have now performed vaginal hysterectomy twenty-nine times; and all the cases recovered from the immediate effects of the operation except two, where I had operated at a distance from the city, and did not see the patients after the operation. A large proportion of these patients remain in excellent health; one has just been married.

The next specimen which I shall show is one of large ovarian abscesses and pus-tubes from a patient who had suffered for some years from recurrent pelvic inflammation of great severity. The mass on the left was as large as two fists, and that on the right about the size and shape of a large lemon. The pus-sac ruptured in delivering it; the pedicles were secured by catgut, as is my custom in all unclean cases. Irrigation, glass drainage, and prompt recovery.

The last specimen is from a woman of thirty, who had never menstruated, but who had suffered intolerable pain every month. On the right the ovary was enlarged and diseased; the tube, however, was extremely slender and imperfectly developed, and did not enter the uterus but seemed to be lost in the broad ligament. On the left, the tube was normal, but the ovary was quite undeveloped, occupying a space as large as a finger-nail and not over one-eighth of an inch in thickness. Both ovaries and tubes were removed. No drainage. Recovery.<sup>3</sup>

SOMETHING ONE GETS IN GERMANY.—There are a great many different inducements for making a trip to Europe. *The College and Clinical Record* states that Professor Parvin, while in Germany, last summer, secured a large number of female sexual organs for use on his obstetrical model. There was no duty paid, and we trust it will not be necessary to apply the principles of protection to this singular industry.

<sup>2</sup> December 7th. All the above patients are doing well, having recovered without accident.

<sup>3</sup> See page 660 of the Journal.

## SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

CHARLES L. SCUDDER, M.D., SECRETARY.

REGULAR meeting, Wednesday, November 4, 1891,  
DR. A. T. CABOT in the chair.

DR. FRANCIS S. WATSON reported

OPERATIONS DONE FOR RADICAL CURE OF HYDROCELE AND INGUINAL HERNIA,<sup>1</sup>

performed at the same time on a patient forty-seven years old.

DR. S. J. MIXTER reported

TWO CASES OF APPENDICITIS, ONE ASSOCIATED WITH UTERINE FIBROID, THE OTHER WITH PREGNANCY.<sup>2</sup>

DR. H. L. BURRELL: The packing with gauze, I fancy, was to secure drainage. I would like to ask how often that was changed.

DR. MIXTER considered the use of iodoform gauze as packing in cases of operation for the relief of abdominal abscess from whatever cause, where the inflamed or suppurating tissues could not be entirely removed, was the best method known for preventing an infection of the general peritoneal cavity. The method first described by Mickulicz, was the one he generally used, small strips of gauze being packed into a large handkerchief of gauze, which is first pushed to the bottom of the cavity. This prevents small fragments of packing being left in the wound. In a few hours the general abdominal cavity is walled off, and the abscess may be treated as in any other part of the body. After the removal of abdominal tumors with extensive adhesions, this method is often more sure to prevent hæmorrhage and sepsis than the use of a drainage-tube.

DR. W. M. CONANT presented

## CASES SHOWING SATISFACTORY RESULTS OF TENDON AND NERVE SUTURE AFTER INJURY.

DR. MIXTER: I must say in regard to the method of temporary fixation of the upper end of the tendon to be sutured, that I was not the one who suggested it.

Professor Nicolaidoni, of Vienna, showed me eleven years ago, how and when it could be used. He used either a needle or temporary stitch to be left in for two or three days.

The temporary stitch I always use when it is possible, and in addition I employ a device which I believe has not been described, and which avoids the tearing and bruising of the cut end and also renders unnecessary the slitting up of the tendon sheaths with the probability of subsequent adhesions.

The method of procedure is this: pass a director or probe up the sheath until its point is well above the cut end, cut down onto the point, and draw the tendon out through the small opening thus made. A temporary stitch of strong silk can then be passed through the tendon well above its cut end, and silk and tendon are then drawn down through the sheath and out of the original wound, the thread being tied to the probe. The stitch for temporary fixation can be put in at the upper opening, and, the ends being united in the usual manner, the silk used for drawing down the tendon is withdrawn. I have used this method in a consider-

able number of cases, and I am sure that the results obtained have been better than could have been expected had the tendons been bruised or their sheaths slit up.

DR. GAY: I think the importance of this subject cannot be exaggerated. I remember one case of a piano player who received a cut across the back of his left hand by a broken window. The result was at the end of six weeks when he came to me, he had complete loss of extension of his fingers, which meant, of course, his living. I told him I would make an effort to pick up those tendons, and I did so. The result was he got a very good laud. At the end of six or seven weeks after the injury those tendons were hard to find. They seemed to be atrophied. One or two seemed to be merely a string, but he got good use of all his fingers, and without suppuration.

Another case: A man was washing his foot in a bowl. The bowl broke and let his foot through, severing the tendo Achillis. That was sewed with catgut, and now at the end of six months, he has almost complete use of the foot. The extension of the tendo Achillis is not quite so free as on the other foot, but practically he has a very good one.

I think it is a matter of a good deal of importance, and I think the effort should always be made to sew the ends of severed tendons together.

DR. MONKS: I should like to ask Dr. Conant what he means by sewing the tendons together, *en masse*.

DR. CONANT: In this special instance I had no trouble at all in separating the sublimis tendons from the profundus, and having caught the ends of the sublimis tendon and the muscular portion together, I passed quilted sutures and united the whole thing without any attempt to separate them; and the profundus the same way, only they were deeper and the rupture very much lower down, and they were part tendons and part muscles, and I picked the whole thing up and sutured them all at once, running the stitch,—usually if you dissect carefully enough out, you can get bundles of muscles for each one of the tendons. What I meant by *en masse* was, I did not attempt to suture the tendon to its corresponding muscle, but swept down and picked up the whole mass of muscles and sutured the tendons without respect to whether it should have gone to the outer or inner side. It is more the idea of getting firm union than any attempt to get special individual motion from each tendon.

DR. CABOT: I had a case this summer which is interesting in connection with this subject as showing the rapidity with which nerve function is recovered. I sutured a median nerve that had been separated for months, where there had been complete loss of sensation through the median distribution. The ends were found, the bulbous portions cut off and the nerve sutured. The interesting point was that sensation began to return in the fingers already at the end of four days.

In regard to the restoration of tendons in which there has been non-union, I had an experience years ago which I think is valuable.

A man came into the hospital with a rupture of the ligamentum patellæ. He could not straighten his leg or walk upstairs. There was a deep sulcus below the patella, where the prominent band of ligament should be. Acting on the experience gained in cases of non-union of bone, his leg was put straight on a splint,

<sup>1</sup> See page 698 of the Journal.

<sup>2</sup> See page 697 of the Journal.

the patella was drawn down into place, and blisters were applied over the depression where the ligamentum patellæ should have been. After the second blister the depression was filled with plastic lymph, so that there was no longer a sulsus, and ultimately that plastic lymph led to a restoration of the tendon. The man was afterwards able to walk upstairs, and could lift his leg.

In small tendons like those at the wrist and ankle, such a course would probably be of little use, but in large tendons like the tendo Achillis, if that were lengthened by non-union, it seems to me such treatment might cause it to be reformed perhaps. Certainly, it answered well in the ligamentum patellæ.

Dr. J. C. MUNRO showed

#### A CASE OF GASTROSTOMY FOR MALIGNANT DISEASE OF THE ŒSOPHAGUS.

The patient is fifty years old; of a healthy family; a wool teamster; always healthy; not alcoholic or venereal. Dyspepsia for two years before present trouble, which began about August 1st of present year, with difficulty in swallowing solids. Two weeks later only soft solids and liquids could be taken. Pain at this time between scapulae. Loss of flesh. Two or three days before entrance to Carney Hospital (September 14th) could not swallow liquids. (Œsophageal bougies stopped at thirteen inches from upper incisors.

Next day (September 15th), Drs. M. F. Gavin, J. J. Minot, F. W. Johnson, and P. Thorndike being present, an opening two inches long was made in the left hypocondrium; the stomach identified, especially by the gastro-phrenic ligament; a portion at the cardiac end drawn out and stitched to wall by heavy silk loops, silver guys having been passed through the outer layers first of all. Very little shock from operation. On following day an opening was made large enough to admit a No. 18 F. soft rubber catheter, which has been worn since. Feeding by the stomach was immediately started, and enemata continued.

For two days the temperature ranged between 99° and 100°, and the pulse between 80 and 90, then both fell to the normal and remained there. The stitches were removed after a week; no pus. Patient up and dressed after removal of stitches.

October 9th. Patient began losing ground although taking and digesting abundant nourishment.

October 20th. While coughing raised blood, evidently from the Œsophagus.

October 30th. Cough distressing and persistent. Rusty sputa. Lungs negative. Losing weight and strength. No leakage beside the tube; no excretion.

November 3d. Steadily losing ground. Cough continues, with bloody sputum, but less severe than before. Pulse irregular and intermittent. Up and about ward most of the day. Complaints of pain between scapulae. Takes two enemata every two hours by stomach, in addition to enemata.

Has been able at times since operation to swallow a very small quantity of water, but has ceased trying to do so lately on account of the vomiting (Œsophageal) and coughing excited.

Dr. MIXTER: I have seen several gastrostomies, but have never seen one where the result was as good as in this case, as far as the retaining of the food that was put in through the tube. There has been almost no leaking. When I returned some days after the operation, the patient was perfectly comfortable, was

being fed; and a week from the time of the operation I found him walking around the yard, clothes on, and the stitches having been taken out the day before. He was perfectly comfortable, and had gained very much from the operation. Of course, now, he has lost very much in flesh and strength, but at that time one certainly could ask no better result from any operation.

Dr. GAY: I would like to ask how far it was from the abdominal parietes to the stomach, how much dragging was necessary to bring the stomach in contact with the abdominal walls?

Dr. MUNRO: Very little. He was emaciated.

Dr. GAY: In the case I had a few years ago, it was five inches I had to draw the stomach up before I could get it in contact with the abdominal walls. There was a good deal of strain upon the stitches. We had no trouble for a fortnight. Then the stitches gave way. He was in a very much worse condition than Dr. Munro's patient. He was bed-ridden. He got relief for about three weeks, and then began to fail, and died in the course of a month or six weeks. I would like to ask if there was any obstacle to intubation in this case?

Dr. MUNRO: We had no Œsophageal tube, otherwise I should have tried it, although the smallest bougie would not pass, but came up against a hard surface thirteen inches from the upper incisors, and I should not have felt authorized in forcing a passage.

Dr. BURRELL reported

#### A CASE OF GASTROSTOMY,<sup>2</sup>

done at the Children's Hospital.

Dr. MUNRO: I think the question of the gastro-phrenic ligament is a pretty important one. I have been careful to examine for this ligament in the subjects at the dissecting-room, and where it is present it is very marked. In Dr. Burrell's case I was not able to recognize it, simply because my finger would not reach it on account of the distension of the abdomen. It, to me, is one of the best guides to the stomach. The transverse colon has been sewed to the abdominal wall in several instances; but I don't see how, with a guide like this and with the left gastro-epiploic artery also, a person could make a mistake. A point that helped me the following day was the wire guys. The wound was a very blind one, and it was pretty hard to see where the knife ought to be plunged in, but with these guys I could easily get my bearings.

Drs. W. H. PRESCOTT and J. E. GOLDTHWAIT reported

#### RESULTS OBTAINED IN 531 CASES OF INTUBATION AND TRACHEOTOMY.<sup>4</sup>

Dr. GAY: I think we have reason to feel greatly indebted to Drs. Prescott and Goldthwait for continuing the records so ably commenced by Drs. Lovett and Munro. The last series of cases, the cases reported to-night, are not so valuable for the sake of comparing the value of the two operations as the cases in which tracheotomy was the only operation, and those in which intubation was the only operation. I mean taking the cases before intubation was put into general use, and compare those with the cases of intubation, say for two or three years after intubation was introduced. In a paper which I read some years ago, the percentage there was a little in favor of tracheotomy,

<sup>2</sup> Publication deferred.

<sup>4</sup> See page 631 of the Journal.

but there was not a very great deal of difference, and those were pretty fair cases for comparison, so far as could be judged. The type of the disease was very much the same in the two series, taking them altogether. I think I am right in saying the feeling at the City Hospital, among the older men particularly, is in favor of trying intubation at first. Speaking generally, it is much more easily done. The parents give their consent more readily, and, I think, the surgeon feels like doing intubation when he would not feel like resorting to tracheotomy. I think I should place intubation first on the list, and if it worked well, I would depend upon it. If it did not, I would resort to tracheotomy. I think, perhaps, tracheotomy will do everything intubation will, and perhaps more. I fancy it will save some cases that intubation will not; at any rate, a certain number of cases get saved with intubation as well as by tracheotomy. I think intubation is a most admirable operation, and in the lighter cases it succeeds very well indeed. It should be remembered that the type of the disease, more than anything else, determines the result.

DR. CONANT: I am very much interested in this subject, not that I know much about either intubation or tracheotomy from actual experience. I have done both a few times. I looked the subject up last year, and I am interested to hear this set of cases that has been so ably worked up. The thing that strikes me at the outset is the difference in percentages. Of the 531 cases we find 96 recoveries, or only 18 per cent. That does not compare favorably with Drs. Lovett's and Muuro's, or with several other men, and I do not know exactly how to account for it, unless we are willing to admit that the operation of intubation is oftentimes performed when tracheotomy ought to be. Since intubation has been introduced, I think there is no question that oftentimes cases have been intubated where tracheotomy ought to have been done. The trouble that I have seen after intubation has been the inability of the average nurse to keep the tube clear. I have always felt that I must be within easy call, or else the tube might be coughed out and the child suffocate. I have felt for a considerable time that the operation for intubation, which at the time it came out was claimed to have a percentage very much larger of recoveries than tracheotomy, was a thing which later on would prove to be fallacious, and the more cases of intubation that are reported the less has grown the percentage of recoveries. In the paper which Dr. Gay speaks of the percentages were very nearly on a par with those of Dr. Lovett. Previous to Dr. Gay's paper the percentages had been larger. In this set of cases the percentage is only 20 per cent., and the combined method, so to speak, only 18 per cent.

DR. LOVETT: The question of intubation is one with which I have had some little practical experience. Does Dr. Prescott know about the cases in the last year, whether the death-rate has been higher than before.

DR. PRESCOTT: Up to January, 1890, the per cent. of recovery was about twenty to twenty-five, and then it fell to fifteen.

DR. LOVETT: With regard to the secondary operation of tracheotomy after intubation, it is a pretty severe case that requires it. After intubation is done, if it does not give relief, it must mean necessarily that either pneumonia has come on or that an extension of the membrane has taken place into the bronchi, and,

of course, in cases of that sort it is a poor outlook for tracheotomy, as death is practically sure under any circumstances. In Dr. Prescott's cases there were only five out of fifty or sixty that recovered where tracheotomy was secondary. In my own experience I do not remember a secondary tracheotomy after intubation that has recovered. In the tracheotomy case there is a good deal of discharge for the first five or six days, of mucus and detritus from the membrane, which comes out of the trachea tube in great quantity. In intubation cases that discharge goes somewhere or other, but does not appear externally; it may be swallowed, but a large part is probably drawn into the bronchi. It has seemed to me in the cases I have watched that the percentage of pneumonia in intubation cases was high. I have for the last two or three months had the house officers watch the cases very carefully in that regard, and in a majority of the cases they have reported to me that pneumonia was beginning or progressing. I saw a case dying last Sunday at the City Hospital, which was characteristic. The respiration was 80; there was no particular cyanosis, but shallow breathing, and the upper lobe of one lung was filled up.

If the cases of intubation are compared with the cases of tracheotomy previous to intubation, we have about the same number. Our percentage of tracheotomy recoveries was about 29; and here in 392 cases of intubation the percentage is nine lower. I am very sure that in the last year the percentage of intubation would be still more unfavorable. What the cause of that is I certainly am not competent to say but my experience in the last month has been much worse than ever before, and it seems to me it will be of interest to perform tracheotomy alone as a primary operation for a little while in the hope of again comparing the two operations. It seems to me that the disappearance, in intubation cases, of all the discharge and the detritus that comes out of the tracheotomy tubes is a very significant matter.

DR. CARO: There is one point I spoke of when intubation first came out, which I think is worth considering when selecting the proper operation. In a case of diphtheria just beginning to affect the larynx, you have a septic disease which has not extended to any appreciable degree below the larynx. Its extension to the deeper parts is greatly favored by the passage of the inspired air, carrying the secretions down with it. If you put in an intubation tube, and these commencing cases are ones in which you would be likely to use intubation, the air that that patient breathes is still entering the lungs through the mouth and throat infected with diphtheria. If, however, at that time, with the disease mainly above the larynx, a tracheotomy tube is introduced below the larynx, the air enters the lungs comparatively free from these diphtheria germs and secretions; so that it seems to me that this suggestion of Dr. Lovett's, that for a while it would be well to give tracheotomy in early cases another fair trial, is a good one. It would be interesting to see whether the tracheotomies would show any better results in these early cases than intubations.

DR. PRESCOTT: As to whether early tracheotomies show better results than early intubations, I cannot tell, except as Dr. Lovett's paper has reported the operations done on the first day as better than on the fourth day, falling from 38 per cent. of recoveries on

the first day to about 14 per cent. on the fourth day; and in the statistics that were reported here to-night the operations done on the first day were only 20 per cent. and the operation done on the third day were 45 per cent. But I think there is a source of error or misunderstanding in these two statistics, in that the time of operation as we took it was after the appearance of laryngeal symptoms. As it was reported in Dr. Lovett's paper, it was the time after urgent dyspnoea had appeared. That makes some difference. Whether it shows that the cases that were intubated were more severe cases, what are described as fulminating cases or not, I don't know; but that is the difference in the two series of statistics as regards the time of operation.

DR. GOLDTHWAIT: I would like to call attention to this table. The series of tracheotomies which covers the same time collected by Romme, show 38.8 per cent. recoveries, and in the series reported by Drs. Lovett and Monro there were 28 per cent. The average of those two would make the per cent. very similar to the per cent. of intubation as it stands there. Why the per cent. of recoveries in the City Hospital cases is so small I cannot say. Cases, of course, are brought there as the last resort. Many of them are in a moribund condition and the tube is put in to let them die easy; and that is one of the great satisfactions of the operation.

It seems to me there is another class of cases in which intubation is the better of the two operations, the class in which there is a great deal of œdema of the larynx, in which the tube is inserted, and seems to squeeze out the œdema, and is coughed out in a few hours, and this is the end of the intubation.

Different authors in writing upon intubation have spoken of ulceration of the larynx as being common. There has not been a case of this that we know of; and out of the 80 cases that recovered there have been, I think, 35 cases found, and seen at least eighteen months from the time of the operation, with a perfect voice and no symptoms which would indicate in the least any ulcerative process which would impede the use of the vocal cords.

DR. PRESCOTT: Dr. Lovett has spoken of the cases of secondary tracheotomy after intubation, and that he has never seen a case recover. I think it is right that the three cases that recovered in the 36 secondary operations should be a little more elaborated. In one of the cases the tube was put in and coughed out within a few hours. No attempt was made to replace it. Tracheotomy was done in twenty-four hours, and the patient went from bad to worse, finally stopped breathing; the heart had stopped and preparations were made to lay the child out. Upon removing the sheet, the child was again breathing.

The second case was one in which the child had been intubed eleven times and coughed out the tube. Before the doctor could get there she had stopped breathing, and immediate tracheotomy was done without attempting to pass the tube. The child is still wearing a tracheotomy tube, it being now eighteen months after the tracheotomy.

The third case was the case of a young Italian who had been intubed a number of times. The relief to the dyspnoea was perfect, but the child did not seem to be able to retain the tube more than a few hours, or at most, a day at a time. Once it coughed out the tube, and during a temporary absence of the senior

who had done the previous intubation, the junior attempted to do the intubation. The child stopped breathing, and immediate tracheotomy was done. The tube was worn some time and then an attempt was made to take it out. It could not be taken out. The minute it was taken out the child stopped breathing, and finally an intubation tube was again passed. The tracheotomy wound healed, the child wore the tube a few days, and finally the tube was removed and the child was discharged well.

Those are the three cases that have recovered after the secondary operation, and it seems to me they are in reality not recoveries after a secondary operation. The secondary operation was not needed except for an emergency and we have nothing to show that two of them, at any rate, would not have recovered just as well if they had been intubed as if they had been tracheotomized.

## Recent Literature.

*Text-Book of Ophthalmoscopy.* By EDWARD G. LORING, M.D., edited by FRANCIS B. LORING, M.D. Part II. Diseases of the Retina, Optic Nerve, and Choroid, their Varieties and their Complications. pp. 260. New York: D. Appleton & Co. 1891.

The appearance of the second volume of Dr. Loring's very valuable text-book on ophthalmoscopy, will call to the minds of many a feeling of deep regret at the death of its learned author. The first volume published some years since has never been equalled by any text-book or monograph upon the subject matter, the ophthalmoscopic appearances of the normal eye. Much was therefore expected of the present volume. Nor is the second volume disappointing. It has not the completeness and rounded character of the first volume, which it would no doubt have had if the author had lived to put it into the form which seemed to him best upon reviewing the matter. Nevertheless, put together as the book is from unrevised copy and note-books, it possesses all the clearness and interest of the first volume, and makes the best text-book upon ophthalmoscopy existing in the English language. Dr. F. B. Loring is to be credited with most excellent judgment in compiling the book from the author's scattered memoranda.

*Text-Book of Comparative Anatomy.* By DR. ARNOLD LANG, Professor of Zoology in the University of Zurich. With preface to the English translation, by DR. ERNST HAECKEL. Translated into English by HENRY M. BERNARD, M.A., and MATILDA BERNARD. Part I. London and New York: Macmillan & Co. 1891.

The volume before us is only the first part of this important work. As it carries us no further than the arthropoda, it contains comparatively little that could be properly discussed in a medical journal. While waiting for the future part that shall treat of more familiar animal forms, we shall say only that the work seems very well adapted for teaching, as far as the actual descriptions are concerned. It is profusely illustrated with really admirable cuts, a few of which are colored. The paper and type are correspondingly good.

THE BOSTON

## Medical and Surgical Journal.

THURSDAY, DECEMBER 31, 1891.

## ANNUS MEDICUS MDCCCXCI.

THE past year has been much less prolific in material for an Annus Medicus than its predecessor. Both the excitement aroused by Koch's tuberculin and the epidemic of influenza were legacies from the previous year. Other epidemics were less common than usual. Medical meetings were largely confined to individual countries, the principal exception being the Seventh International Congress of Hygiene and Demography which met in London, in August.

## EPIDEMICS.

The only epidemic disease which has assumed prominence during the year has been influenza or the "grippe." At the close of 1890 it had traversed the earth and appeared to be dying out except perhaps in China. In January and February several districts in Asia were visited. In China the disease became a fatal epidemic. In March it reappeared with much energy in Chicago, in New York and several cities in the United States. In April the death-rate of the State of New York rose to thirty per thousand, the great rise being due to the diseases of the respiratory organs, secondary to the grippe. The course of the epidemic was perhaps more erratic than in 1890, since this year neighboring towns and States were very differently affected. Boston suffered very little, its death-rate hardly rose at all, while other cities in New England were not so fortunate. During the spring, England passed through a very serious epidemic of influenza. Appearing in Sheffield during the first half of April it spread over the island, increasing in severity until well into June. More deaths were recorded as due to the disease during the first week in May than in any week in 1890. In some of the cities the death-rate rose to over forty. A few places on the Continent of Europe reported outbreaks but no country suffered to the same extent as did Great Britain. In May, we find reports of serious outbreaks in Norway, Southern Russia, Alaska, Egypt and parts of Germany.

During the summer influenza was reported from Spain and Portugal, and in September it broke out with great energy in Australia. In October it took a fresh start in Europe. It apparently revived in several places at about the same time and from these foci spread to adjacent districts, but not with anything like the rapidity which marked its progress in 1889. The east of Scotland and the west of England were the centres in Great Britain. In November many parts of France reported severe outbreaks, the death-rate in Paris rose suddenly, while some of the cities of northern Germany were visited as severely as in 1889, and in Russia it existed in nearly all parts of the country. A little later it appeared in Vienna. During the first half of December it spread and increased in severity in most northern European countries, the principal centres being Hamburg, Berlin and St. Petersburg, and rumors of its existence were heard in the United States. By the middle of the month no doubt remained of its wide distribution in this country.

By the first of the year cholera had disappeared from Europe, and did not reappear during 1891. In May, it was reported that there was none in the Ottoman Empire. In June, it reappeared in Aleppo in Syria, undoubtedly a reproduction of the epidemic of last year. On July 11th, a few days before the commencement of religious ceremonies in Mecca, it appeared among the pilgrims, and continued until they dispersed. From 1881 to 1891, cholera has prevailed five times in the Hedjaz, and each time it was previously declared at the Red Sea ports in Egypt. It appears to be imported by pilgrim vessels plying between Bombay and the quarantine station at Camaran. The eastern epidemic, during the summer months, spread to Antioch and Alexandria. In August, it had disappeared from the Hedjaz, but the Aleppo epidemic continued well into October, spreading to Damascus and Hodeida. In September, cholera was reported epidemic in Amoy, China. In Calcutta there were more deaths than usual.

Yellow fever has not visited the United States during the year. It appeared in Rio Janeiro in the spring, and continued during the summer and into the autumn, at which time it was reported as worse at Santos and in other Brazilian towns than in Rio Janeiro. As late as December the disease was reported as epidemic in different districts. In the West Indies, the disease was about as prevalent as usual in the middle of the summer. The port of Vera Cruz was also infected.

Typhoid fever pursued about the same course as usual during the year. In Italy, Florence was attacked by a severe epidemic during the first weeks of the year. In this vicinity, Wakefield, Mass., and Valley Falls, R. I., suffered from slight epidemics.

In January, on account of an epidemic of small-pox in the northern part of Mexico, a quarantine was established along the Rio Grande. Later, in the autumn, certain provinces in Canada reported a large

number of cases. In Russia it broke out with severity in the famine-stricken districts. With these exceptions and a few isolated cases, the disease has not attracted particular attention during the year.

#### MEDICAL LEGISLATION.

Among the laws passed during the year, of interest to the medical profession, we may mention the following: The Immigration Law passed by the last Congress requires medical inspection of all immigrants on arrival. All idiots, insane people, paupers, or persons likely to become a public charge, or persons suffering from a loathsome, dangerous, contagious disease, as well as felons and assisted persons, are to be sent back to the country from which they came.

Congress has also passed an act establishing five stations for the inspection of meat which is destined to be exported. The principal duty of the inspector appears to be to hunt for trichinae.

The State of Alabama has passed a law requiring all physicians who are not graduates of a reputable medical college to obtain a certificate of qualification from a board of medical examiners.

The State of Arkansas has passed a law allowing the Board of Medical Examiners, after trial, to revoke the license to practice of a physician, if convicted of unprofessional conduct.

The State of Nebraska has passed a law requiring a certificate from the State Board of Health and graduation from a legally chartered medical school or college, before a license to practice is allowed.

Among the States in which bills, regulating the practice of medicine have been defeated, may be mentioned Massachusetts, Rhode Island and Pennsylvania. The latter State has already a registry law. Massachusetts is now one of five States only in which the practice of medicine is unrestricted by law.

The New York State medical practice law passed during the preceding year went into effect. It provides that no one shall practice medicine in the State without previously obtaining a license from the State Board of Medical Examiners.

In Massachusetts a law was passed requiring the detention of inmates of State penal and charitable institutions who are suffering from syphilis in a contagious form, until the disease is no longer contagious.

The State of Maine requires all persons having charge of an infant with sore eyes to report the fact to a physician. It has also passed a law to provide for the registration of vital statistics.

In Massachusetts an attempt was made to restrict the use of an acid in the manufacture of various articles, but it resulted merely in prohibiting its use in children's toys and confectionery.

The United States Supreme Court has decided that a court may not order a medical examination of a person in a civil case against his or her will.

The Municipal Court of Boston has decided that a druggist may sell cigars on Sunday, as a drug to be used for the cure of catarrh.

#### NEW METHODS OF TREATING TUBERCULOSIS.

At the beginning of the year the whole medical world was in an extraordinary condition of excitement over the recent publications of Prof. Robert Koch, of Berlin. In almost all of the large hospitals of the world tuberculin was injected into patients suffering from tuberculous disease. The most peculiar phase of the excitement was the readiness with which a large number of physicians believed that they could see great improvement in the patients under treatment. Already in February many observers were beginning to doubt the great therapeutic value of the new remedy. This feeling of doubt was much strengthened by an adverse criticism by Professor Virchow, on February 11th; and from this time on the excitement steadily subsided, and in the majority of cities the treatment was suspended. In Berlin, however, a large number of cases continued to be injected with tuberculin. Towards the first of the summer those who were still using tuberculin became convinced that the reaction observed after injection of the fluid was undesirable, and they began to give it in smaller doses. The fluid was analyzed by Hunter, Cheyne, Klebs and others, who separated from the complex tuberculin different substances which appeared to have different therapeutic action. In October, Koch himself described a process by which he separated what he considered the active principle of the fluid. At present, it must be said that the therapeutic value of tuberculin is still unknown, and that a long time and much work must elapse before its true value is settled.

On account, undoubtedly, of the interest taken in the therapeutics of tuberculosis, a large number of methods for the cure of consumption were published during the year. Liebreich proposed the use of cantharidate of potash subcutaneously. By this method several observers in Berlin obtained results as striking as those obtained by tuberculin.

In France, Professor Germain Sée advised treatment of pulmonary tuberculosis by the continued inhalation of air under pressure, containing creasote and eucalyptol. Bernheim, Picq and Bertin suggested the injection of goat's blood, and Héricourt and Richet the injection of blood serum of the dog, both of these animals being naturally immune to the disease. Later M. Lannelongue published an account of his method of deep local injections of solutions of chloride of zinc outside of, and around the spreading edge of tuberculous tissue.

Diamantherger, Picot, Weil and others advocated the subcutaneous injection of iodoform, guaiacol and other agents, in sterilized olive oil.

In this country, injections of gold and manganese were suggested by White, iodoform by Gibbes and Shurley, and vaccine lymph by Tyndale.

## MISCELLANY.

In connection with the study of the biology and chemistry of the lower animals, the investigation of natural and acquired immunity in infectious disease, may almost be said to have developed during the year. It is impossible in the limits of this review to do more than mention the subject; but we may call attention to the researches of Brieger and Fränkel on acquired immunity in diphtheria, of Behring and Kitasato in tetanus, of Hankin, Ogata and Wooldbridge in anthrax, and of Vassale, Montanari and G. and F. Klemperer in pneumonia. It is surely not unreasonable to hope that important therapeutic gain may ultimately result from these and similar investigations.

As most civilized countries take a census on decennial years, the results became known during the past year. The population of the United States amounts to about 63,000,000, an increase of over 12,000,000 during the past decade. The population of the United Kingdom is about 37,000,000. Ireland has less than 5,000,000, and London, including the outer ring, 5,600,000. Canada counted only 4,800,000, an increase of one-half a million during the last ten years. France a little over 38,000,000, and Germany 49,000,000. A recent estimation of the population of the earth for this year is 1,480,000,000.

On October 13th, Prof. Rudolf Virchow celebrated his seventieth birthday. Advantage was taken of this occasion by his many admirers, to express their appreciation of the work which he has done for medical science. It is probable that no medical man has ever received such a universal tribute from his professional colleagues as was bestowed upon him on this occasion. Subscriptions were raised and memorial meetings were held in different parts of the world. In Berlin, an enormous gold medal weighing five or six pounds, was presented to him, and congratulatory addresses poured in from all directions.

An important step toward higher medical education in the United States was inaugurated by the Harvard Medical School and the University of Pennsylvania, which institutions almost simultaneously announced an increase from three to four years in the time required to obtain the degree of M.D. This requirement will go into operation in the case of the former school in 1892, and with the latter in 1893. The question of the compulsory five years' course has been much discussed, and finally adopted in England.

An institution for the study of infectious diseases has been opened in Berlin, and placed under the charge of Prof. Robert Koch. These diseases are to be systematically investigated as well as all questions connected with immunity. In England, the British Institute of Preventive Medicine has finally been officially allowed to exist. For a long time the granting of a charter to this institution was combated by antivivisectionists.

Among the associations which have been organized during the year may be mentioned, the Pan-American Medical Congress. This Congress is to meet in Washington, in October, 1893, and is to be composed of delegates from all countries on the two American continents. Dr. William Pepper, of Philadelphia, was elected President, and Dr. Charles A. L. Reed, of Cincinnati, Secretary. The National Association of Military Surgeons of the National Guard of the United States was organized in Chicago, the object being the advancement of military and accident surgery, and all things pertaining to the health, usefulness and welfare of the civilian soldier.

The Harvard Medical School Association was organized in Boston to furnish opportunities for enjoyment and sociability among the graduates, and to increase and foster the interests of the Medical School and University. In New York, a Harvard Medical Society was organized to be composed of graduates of the Harvard Medical School, residing in New York.

A Leprosy Commission, sent from England to India, and there joined by Indian members, has been investigating leprosy in all its relations. A report has been received that they have succeeded in cultivating the leprosy bacillus.

The winter of 1890-91 was a very severe one in Europe. Much hardship was caused in several countries, and many persons died of exposure, especially in the warmer districts, where they did not know how to protect themselves. In Paris public places were converted into places of refuge.

Several million peasants in Russia have been reduced to great distress by a series of failures of crops. The exportation of cereals has been forbidden and everything which could possibly be used for food has been prepared and eaten. Small-pox, typhus fever, and influenza have broken out in the afflicted districts.

Considerable excitement was roused during the summer, both in Paris and Berlin, over the report of certain cases in which cancerous tissue had been grafted into patients as an experiment. In Paris, M. Cornil described a case before the Academy of Medicine, not giving the name of the operating surgeon. The proceeding was strongly condemned by all of those present. In Berlin, a lawyer accused Professors Bergmann and Hahn of similar experimenting.

The novel New York law establishing electricity as a means of executing criminals has been further tested, five murderers having been killed during the year. The details were essentially the same as in the case of Kemmler, last year. Early in July, four men in succession were executed at Sing Sing. On account of the provision of the law, forbidding the publication of details, many conflicting accounts were circulated. The official reports announce that unconsciousness was instantaneous and that after three or four contacts of the current, each lasting a few seconds, death was certain.

We have heard a good deal in America during the year, from the daily press, of a cure for drunkenness, the proprietor of which is one Keeley, who has opened a sanitarium in Dwight, Ill., and who advertises to cure drunkenness by his so-called bichloride of gold treatment. This particular salt of gold is so unstable that it may be said not to exist, and different analyses of the substance have failed to reveal any gold at all, but the cure has been very popular, and branch institutions have been started in different parts of the country.

Among the calamities which have killed and injured many persons during the year may be mentioned the earthquake in Japan. On October 28th, according to a recent estimate, about 7,500 persons were killed and 10,000 injured; 90,000 buildings were wholly destroyed and 400,000 people made destitute. By the sinking of the steamer *Utopia* at Gibraltar, on March 17th, over 560 persons were drowned. The floods in Spain in September, destroyed many hundred lives and much property.

#### MEDICAL CONGRESSES AND MEETINGS.

Among the more important meetings of Medical Congresses and Societies during the year were the following:

The American Medical Association held its forty-second annual meeting in Washington, May 5th to 8th. The Massachusetts Medical Society held its one hundred and tenth annual meeting in Boston, June 9th and 10th. The New Hampshire Medical Society celebrated its hundredth anniversary, June 15th to 17th. The first annual business meeting and dinner of the Harvard Medical School Association was held in Boston, June 23d. The Association of Military Surgeons of the National Guard of the United States organized and held its first annual meeting in Chicago, September 18th. The American Association of Obstetricians and Gynecologists held its fourth annual meeting in New York, September 17th to 19th. The Second Triennial Congress of American Physicians and Surgeons met in Washington, September 22d to 25th. The component National Associations and Societies which form this Congress, each of which held its annual meeting during the session of the Congress are as follows: The American Surgical Association, Ophthalmological Society, Otological Society, Neurological Association, Gynecological Society, Dermatological Association, Laryngological Association, Climatological Association, Association of American Physicians, Association of Andrology and Syphilology, Orthopedic Association, Pediatric Association, Association of Anatomists, Physiological Society. The American Electro-Therapeutic Association held its first annual meeting in Philadelphia, September 24th to 26th. The Mississippi Valley Medical Association held its seventeenth annual meeting in St. Louis, October 11th to 16th. The American Public Health Association held its nineteenth annual meeting in Kansas City, October 19th to 23d. The Southern Surgical and Gynecologi-

cal Association held its annual meeting in Richmond, November 10th to 12th.

The Fifth French Congress of Surgery was held at Paris, March 30th to April 1st. The Twentieth German Surgical Congress was held in Berlin, on April 1st to 4th. The Tenth German Congress for Internal Medicine was held at Wiesbaden, April 6th to 9th. The Society of Hypnology met in Paris, on July 20th. The Congress for the Study of Tuberculosis was held in Paris, July 27th to 31st. The British Medical Association held its annual meeting at Bournemouth, July 28th to 31st. The Seventh International Congress of Hygiene and Demography was held in London, August 10th to 17th. There were nearly three thousand delegates present, from all the civilized countries of the world. The business was divided among ten sections, and many valuable papers were presented. The German Congress of Naturalists and Physicians was held at Halle, September 21st to 23d.

#### LECTURES.

In connection with established lectureships in the United States and Great Britain, the following lectures and orations were delivered:

The Mütter Lectures in Philadelphia, by Roswell Park, M.D., of Buffalo, on Selected Topics in Surgical Pathology; the Shattuck Lecture before the Massachusetts Medical Society, by Edward Cowles, M.D., on "Neurasthenia and its Mental Symptoms"; the Croonian Lectures, by J. Burdon Sanderson, M.D., F.R.S., on "The Progress of Discovery Relating to the Origin and Nature of Infectious Diseases during the last Twenty-five Years"; the Morton Lecture, by Oliver Pemberton, F.R.C.S., on "Cancer and Cancerous Diseases"; the Cavendish Lectures, by T. Lauder Brunton, M.D., D.Sc., LL.D., F.R.C.P., F.R.S., on "Elimination and its Use in Preventing and Curing Disease"; the Cameron Lecture, by Sir Joseph Lister, Bart., F.R.S., on "A Lesson in Antiseptic Surgery"; the Harveian Lectures, by J. F. Goodhart, M.D., on "Common Neuroses"; the Letsomian Lectures, by Stephen Mackenzie, M.D., F.R.C.P., on "Anæmia, its Pathology, Symptoms and Treatment"; the Lumenian Lectures, by W. H. Broadbent, M.D., F.R.C.P., on "Structural Diseases of the Heart Considered from the Point of View of Prognosis"; the Goulstonian Lectures, by Thomas Oliver, M.D., F.R.C.P., on "Lead Poisoning in its Acute and Chronic Manifestations"; the Erasmus Wilson Lectures, by J. Bland Sutton, F.R.C.S., on "The Value of Comparative Pathology to Philosophical Surgery"; the Milroy Lectures, by R. Thorne Thorne, M.B., F.R.S., F.R.C.P., on "Diphtheria, its Natural History and Prevention"; the Bradshaw Lecture, by Dr. Alldrich, on "Duodenal Indigestion"; the Harveian Oration, by W. Howship Dickinson, M.D., F.R.C.P., on "Harvey, in Ancient and Modern Medicine"; the Hunterian Oration, by Fletcher Beach, M.B., F.R.C.P., on "Physiological Medicine in John Hunter's Time, and the Progress it has since Made."

## NECROLOGY. — FOREIGN.

J. G. F. Baillarger, M.D., formerly president of the Académie de Médecine, died in Paris, December 31, 1890, aged eighty-two.

Thomas Graham Balfour, M.D., F.R.C.P., F.R.S., surgeon-general, retired, honorary physician to the Queen, died January 17, aged seventy-seven.

Edward Bellamy, F.R.C.S., senior surgeon to Charing Cross Hospital, London, died January 4, aged forty-eight.

Sir James Risdon Bennett, M.D., formerly president of the Royal College of Physicians, London, died December 14, aged eighty-two.

Giambattista Borelli, M.D., senator of the kingdom of Italy, died January 10, aged seventy-eight.

Richard G. H. Butcher, M.D., F.R.C.S.I., the inventor of different surgical apparatus, died in Dublin, March 21, aged seventy-two.

Carl Rudolf Braun, Ritter von Fernwald, professor of obstetrics and gynecology in the University of Vienna, etc., died March 28, aged sixty-nine.

Wilhelm von Etlinger, physician accoucheur to the Empress of Russia, died November 8, aged seventy-one.

George Gulliver, M.B., F.R.C.P., demonstrator of morbid anatomy at St. Thomas's Hospital, London, died January 11, aged thirty-nine.

Nicolas Gutierrez, M.D., professor of pathology in the University of Havana, died in January, aged about ninety.

Edmund Hartnack, who was the first to introduce immersion into microscopy, died in Potsdam, in January.

Sir Prescott Gardner Hewett, Bart., F.R.C.S., one of Her Majesty's sergeant-surgeons, and surgeon to the Prince of Wales, died June 20.

Ignatius Hirschler, a writer on diseases of the eye, died in Buda Pesth, November 11, aged sixty-eight.

Eugene Jendrassik, professor of physiology in the University of Buda Pesth, died in March, aged sixty-seven.

Friedrich W. Scanzoni von Lichtenfels, emeritus professor in the University of Würzburg, the author of many works on gynecology and obstetrics, died on June 12, aged sixty-nine.

W. Orlando Markham, M.D., F.R.C.P., formerly editor of the *British Medical Journal*, Gonstantian lecturer, etc., died January 23, aged seventy-two.

John Marshall, F.R.S., F.R.C.S., LL.D., M.D., professor of anatomy to the Royal Academy, etc., died in London, January 1, aged seventy-two.

Ernst Fleischl von Marxow, professor of physiology in the University of Vienna, died October 22, aged forty-five.

Heinrich Opensteiner, M.D., who had been the body physician of the Emperor Maximilian of Mexico, died in Vienna, January 25, aged seventy-one.

Henri Roger, M.D., ex-president of the Académie de Médecine, died in Paris, in November, aged eighty-two.

Franz Christoph von Rothmund, M.D., formerly professor of surgery in the University of Munich, died early in December, aged ninety-two.

Wilhelm Stricker, M.D., the author of many medical writings, died in Frankfort-on-the-Main, March 4, aged seventy-six.

William Henry Stone, M.D., F.R.C.P., F.R.C.S., physician to St. Thomas Hospital, Croonian, Lumleian and Harveian lecturer, died in London, July 5, aged sixty-one.

Henry Gawen Sutton, M.B., F.R.C.P., lecturer on pathology at the London Hospital, died June 9, aged fifty-five.

Hugh Owen Thomas, F.R.C.S., surgeon and inventor of different surgical appliances, died in Liverpool, January 6.

Carl Wedl, professor of histology in the University of Vienna, died September 23, aged seventy-six.

W. Weiss, professor of surgical pathology at the Bohemian University of Prague, died about July 10, aged fifty-six.

Friedrich Wiegner, professor of internal pathology in the University of Strasburg, died in January, at the age of seventy.

## NECROLOGY. — UNITED STATES.

Joseph W. Alsop, M.D., lieutenant-governor of Connecticut, died June 24, aged fifty-two.

Jesse P. Bancroft, M.D., for twenty-five years superintendent of the New Hampshire Asylum for the Insane, died April 30, aged seventy-five.

Fordyce Barker, M.D., LL.D., professor emeritus of clinical midwifery and the diseases of women at the Bellevue Hospital Medical College, etc., died in New York, May 30, aged seventy-three.

Henry F. Campbell, M.D., confederate surgeon, ex-president of the American Medical Association, died in Augusta, Ga., December 15, aged sixty-eight.

A. H. Chessmore, M.D., president of the Vermont State Board of Health, died January 27, aged fifty.

Frank Donaldson, M.D., emeritus-clinical professor of diseases of the throat and chest, University of Maryland, died December 8, aged sixty-eight.

Morius Duval, M.D., brevet medical director and commodore United States Navy, died February 21, aged seventy-three.

Thomas P. Gary, M.D., president of the Florida Medical Association, died June 10, aged fifty-six.

Alfred Hosmer, M.D., ex-president of the Massachusetts Medical Society, etc., died in Watertown, May 11, aged fifty-eight.

Hosmer A. Johnson, M.D., professor of general medicine, emeritus, Chicago Medical College, died February 26, aged sixty-nine.

Christopher Johnston, M.D., professor of surgery emeritus in the University of Maryland School of Medicine, died October 11, aged sixty-nine.

Joseph Leidy, M.D., LL.D., professor of anatomy in the University of Pennsylvania and an eminent naturalist, died April 30, aged sixty-eight.

George B. Loring, M.D., of Salem, Mass., United

States minister to Portugal, died September 14, aged seventy-four.

George Hinckley Lyman, M.D., of Boston, Mass., died in London, August 19, aged seventy-two.

Richard Lee McDonnell, M.D., professor of clinical medicine at McGill University, Montreal, died July 31, aged thirty-five.

Edward Maynard, M.D., D.D.S., dental surgeon and inventor, died in Washington, May 3, aged seventy-eight.

John J. Milhan, M.D., surgeon and brevet brigadier-general United States Army, died in New York, May 8, aged sixty-three.

J. Dickinson Miller, M.D., brevet medical director and commodore United States Navy, died January 29, aged eighty.

John S. Messersmith, M.D., brevet medical director and commodore United States Navy, died in Lancaster, Pa., February 16, aged eighty-one.

Charles T. Parkes, M.D., professor of surgery in the Rush Medical College, Chicago, died March 28, aged forty-eight.

F. H. Potter, M.D., clinical professor of laryngology at the University of Buffalo, died July 16, aged thirty-one.

Thomas B. Reed, M.D., surgeon to the Presbyterian Hospital, Philadelphia, died April 1, aged fifty-six.

Thomas L. Smith, M.D., brevet medical director and commodore United States Navy, died in Brooklyn, August 14, aged ninety-one.

D. Humphreys Storer, LL.D., M.D., died in Boston, September 10, aged eighty-seven.

James K. Thacher, M.D., professor of physiology in Yale University, died April 20, aged forty-three.

J. L. Vandervoort, M.D., for more than fifty years librarian of the New York Hospital Medical Library, died July 20, aged eighty-two.

James W. White, M.D., D.D.S., president of the S. S. White Dental Manufacturing Company, died in Philadelphia, May 27, aged sixty-seven.

#### NECROLOGY. — MASSACHUSETTS MEDICAL SOCIETY.

Fordyce Barker, LL.D., M.D. (Honorary), of New York, N. Y., died May 30, aged seventy-three.

Buckminster Brown, M.D., of Boston, died December 24, aged seventy-two.

William Cogswell, M.D., of Bradford, died August 15, aged seventy.

William Wellman Dow, M.D., of Somerville, died May 8, aged fifty-seven.

Solney Drinkwater, M.D., of Haverhill, died November 20, aged seventy-nine.

Honore Dupue, M.D., of Dorchester, died August 7, aged eighty-one.

Henry Dyer, M.D., of New York, N. Y., died September 21, aged eighty-seven.

George Eliot, M.D., of Boston, died May 22, aged twenty-five.

William Carroll Emerson, M.D., of Boston, died October 8, aged thirty-seven.

Lorenzo Smith Fox, M.D., of Lowell, died June 23, aged fifty-one.

Alfred Charles Garratt, M.D., of New York, N. Y., died June 30, aged seventy-eight.

Joseph Green Stevens Hitchcock, M.D., of Foxboro', died August 24, aged sixty-eight.

Alfred Fairbanks Holt, M.D., of Cambridge, died December 28, 1890, aged fifty-two.

Alfred Hosmer, M.D., of Watertown, died May 14, aged fifty-eight.

John Alban Kite, M.D., of Nantucket, died in October.

Harvey Knight, M.D., of Bellevue, Fla., died March 26, aged forty-six.

Abel Cutting Livermore, M.D., of Stow, died March 15, aged sixty-six.

George Edward Livermore, M.D., of Lowell, died September 4, aged thirty-six.

John Dudley Lovering, M.D., of Newton Highlands, died March 18, aged sixty-four.

George Hinckley Lyman, M.D., of Boston, died August 19, aged seventy-two.

John Howell Mackie, M.D., of New Bedford, died March 5, aged sixty-five.

Prince Woodman Page, M.D., of Boston, died September 29.

Ralph Alfred Parsons, M.D., of West Roxbury, died April 3, aged twenty-nine.

Franklin Fletcher Patch, M.D., of Boston, died November 12, aged seventy-six.

Dom Pedro, Secundo, Emperor of Brazil (Honorary), died December 4, aged sixty-six.

Peter Pineo, M.D., of Hyannis, died September 10, aged sixty-six.

Horace Richardson, M.D., of Boston, died June 18, aged sixty-one.

Edward Sawyer, M.D., of Bridgewater, died December 21, aged fifty-three.

Preston Sheldon, M.D., of Wakefield, died April 17, aged thirty-seven.

David Humphreys Storer, M.D., of Boston, died September 10, aged eighty-seven.

Joseph Herman Streeter, M.D., of Roxbury, died May 30, aged seventy.

William Howland Taylor, M.D., of New Bedford, died July 20, aged thirty-seven.

Warren Tyler, M.D., of North Brookfield, died April 18, aged seventy-two.

Arthur Edouard Zepheren Vincelette, M.D., died July 3, aged thirty-seven.

Franklin Cooley Warren, Jr., M.D., of Boston, died January 2, aged thirty-seven.

Joseph Huckins Warren, M.D., of Boston, died March 24, aged fifty-nine.

Warren Jacob Whitney, M.D., of Dorchester, died March 11, aged eighty.

The Society has lost thirty-six members during 1891, whereas in 1890 forty members died. The average age is the same for the two years, almost exactly sixty.

## MEDICAL NOTES.

AN EXTRA NUMBER.—On account of a peculiarity in the calendar this year, this volume of the JOURNAL consists of twenty-seven numbers, which increase does not involve any decrease in the size of any former or future volume.

FIRE IN AN INSANE ASYLUM.—The female division of the Eastern Michigan State Insane Asylum at Pontiac was entirely destroyed by fire during the past week. This fire again showed the necessity for a fire-proof construction for hospitals for the insane. Although it is hoped that no inmates were burned to death, it was only by hard work and good luck that the loss of life was not large.

## BOSTON AND NEW ENGLAND.

INFLUENZA AMONG THE POLICE.—According to the report of the Superintendent of the Police Department, seventy policemen, or one in every twelve members of the department were on the sick list on Monday.

MEDICAL INSPECTION IN THE PUBLIC SCHOOLS.—The Boston School Committee have recently passed an order that the request of the Board of Health to appoint a number of medical inspectors of the schools be granted, the School Board assuming no responsibility. The object and plan of this system of inspection will be found on page 360 of the JOURNAL for October 1st. This system may at present be said to be experimental. Fifty physicians will be appointed, and the inspection of the schools will probably begin on the first of the year.

THE DEATH-RATE OF BOSTON last week was 33 per thousand, the total number of deaths being 292, as against 187 for the corresponding week last year. Although only three deaths were reported as directly due to the epidemic of influenza, it is evident that this disease is largely responsible for the very high rate. The deaths from consumption numbered 32, from pneumonia 57, from bronchitis 27, and from "heart-disease" 20. Seventy-five of those who died were over sixty years of age.

LEGACY FOR THE LOWELL HOSPITAL.—Mrs. Thomas Talbot, of Lowell, has given to the Lowell City Hospital an endowment of \$5,000 in memory of her husband, the late Governor Talbot.

THE WALTHAM HOSPITAL.—The charity hall in aid of the Waltham City Hospital is to be held in the Park Theatre, on January 1, 1892.

## NEW YORK.

INFLUENZA.—The influenza has continued to increase in the community, and the number of deaths during the week ending December 26th, was largely in excess of the mortality of the previous week. On the day before Christmas the deaths from all causes amounted to 150, the largest number reported in the city on one day for several months, and of these, twelve were attributed to influenza and complications. On Christmas day the total number of deaths reported was 159, and of these, ten were attributed to the grip.

## METEOROLOGICAL RECORD.

For the week ending December 12, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Date.	Baro- meter	Thermom- eter.	Relative humidity.	Direction of wind.	Velocity of wind.	We'thr.	Rainfall in inches
Daily mean.	Daily mean.	Maximum. Minimum.	Daily mean.	8.00 A. M. 8.00 P. M.	8.00 A. M. 8.00 P. M.	8.00 A. M. 8.00 P. M.	
S... 6	29.97	50 56	44 51	46 44	S.W. S.W.	15 6	O.

#### AN ARMY MEDICAL BOARD.

An Army Medical Board will be in session in Chicago, Illinois, during February, 1892, for the examination of candidates for appointment in the Medical Corps of the United States Army, to all existing vacancies.

Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before January 15, 1892, for the necessary invitation, stating the date and place of birth, the place and state of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in the hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a Regular Medical College, as evidence of which, his diploma must be submitted to the Board.

Further information regarding the examinations may be obtained by address, from the Surgeon-General U. S. Army, Washington, D. C. — ST. EBERHARDT, *Surgeon-General U. S. Army.*

#### SOCIETY NOTICES.

**SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.**—This Section will hold its regular monthly meeting at 19 Boylston Place, Wednesday, January 6, 1892, at 8 o'clock, P. M.

Dr. George W. Gay will present the subject of "Gangrenous Hernia, its Treatment."—A Report of Six Cases.

Dr. Maurice H. Richardson will report a second successful case of Circular Enterorrhaphy for Gangrenous Hernia. Dr. Edward H. Bradford, Dr. Herbert L. Burrell, and Dr. Arthur T. Cabot will contribute to the discussion cases of gangrenous hernia illustrating methods of treatment and the various complications arising.

CHARLES L. SCUDDER, M.D., *Secretary.*

**BOSTON SOCIETY FOR MEDICAL OBSERVATION.**—A regular meeting of the Society will be held at 19 Boylston Place, on Monday, January 4, 1892, at 8 o'clock P. M.

Dr. W. M. Conant will read a paper on "Imperforate Rectum." Discussion by Drs. A. T. Cabot, M. H. Richardson, W. D. Hodges and others.

Dr. Morton Prince will read a paper entitled, "Three Cases of Traumatic Functional Paralysis—Two of Twenty-nine and One of Twenty-eight Years' Duration; A Contribution to the Progress in Traumatic Neuroses."

A case of traumatic functional monoplegia (Charcot's type), with paresis of the face muscles will be shown.

JOHN C. MUNRO, M.D., *Secretary.*

#### RECENT DEATHS.

SIMEON TUCKER CLARK, M.D., died of apoplexy in Lockport, N. Y., December 24th. He was born at Canton, Norfolk County, Mass., on October 10, 1830. He received the degree of M.D. from the Berkshire Medical College, and in 1861, settled in Lockport, where he continued to practise up to the time of his death. He was well known as an alienist, writing many articles on insanity which were accepted as of the highest worth by American and European authorities, and for the past six years he occupied the Chair of Medical Jurisprudence in the Niagara University at Buffalo. He was also interested in literature, and was the author of several poems. From the time of its organization Dr. Clark took an active interest in the New York State Medical Association, and he was always a prominent figure at its annual meetings.

HENRY FRASER CAMPELL, M.D., of Augusta, Ga., died December 15th, after an illness of some weeks, at the age of sixty-seven. He began the study of medicine at the age of fifteen, in the Medical Department of the University of Georgia. During the war he was commissioned as a surgeon in the Confederate Army. After the war he was called to New Orleans, where he filled the chair of anatomy, and later of surgery, in the New Orleans School of Medicine, but on account of ill-health returned to Augusta. He was elected President of the American Medical Association in 1885, having been the second Southern man to hold this position.

R. A. KINLOCK, M.D., died in Charleston, S. C., December 23d, aged sixty-five. He had been dean of the South Carolina Medical College and Vice-president of the American Medical Association.

BUCKMINSTER BROWN, M.D. (Harv. 1844) M.D.S.S., died at Auburndale, December 24th, aged seventy-two.

FREDERICK BEDFORD, M.D. (N. Y. Univ. 1859), died in New York, December 28th, aged fifty-four.

JOHN MINTER, M.D., Inspector-General of Hospitals, and honorary physician to the Queen, died in England, December 16th, aged seventy-five.
